Chorea was certainly rheumatic in its nature, whether occurring before, after, or during the progress of the other phenomena of the disease. The embolic theory of its origin, which at one time had a strong head on the profession, was now never heard of; chorea is a form of rheumatism, as well as polyarthritis acuta, endocarditis, pericarditis, and tonsillitis. Salicylic acid has no effect on chorea, erythema nodosum, or purpura, but the difference between the tissues affected accounts for this. In conclusion he offered the most hearty thanks for his paper to Dr. Cheadle, who had left nothing for anyone else to say upon the subject.

Dr. Lees differed with Dr. Cheadle only in one point: erythema nodosum had no connection whatever with rheumatism, but was as distinct as scarlet fever or measles, coming and going in the same person again and again, and never causing a cardiac murmur. No person with acute rheumatism ever develops erythema nodosum; other erythemata? yes, but nodosum never, or but occasionally, and at long intervals between the two affections.

Chorea is essentially rheumatic, is a rheumatic condition, and fright is much exaggerated as a determining cause; a rheumatic child is as liable to be frightened as any other, but no harm results if there is no rheumatic history.

Chorea is the first indication of rheumatism, and the patient will be found, subsequently, to develop the remaining symptoms of the disease.

In chorea the knee-jerk is normal, or exaggerated, or absent; no neurotic theory can explain this. There is, however, evidence of a blood-poison acting on the spinal cord or the peripheral nerves. Occasionally there is a rapid dilatation of the heart in rheumatic children, which is due to inflammation. If there is an acid poison in the blood, it may act as lactic acid would, or if not, as a direct toxin.

The rheumatic state is produced by a blood-poison, which may be eliminated in the tissues by a micro-organism. He had examined the brain and cord in a case that had a fatal termination, but the evidence was entirely of a negative character. Rheumatism is often associated with tonsillitis; diphtheria is due to a microbe poisoning the system by toxin which it elaborates, and the rheumatic microbe may similarly poison the fauces and give rise to the tonsillary affection.

In some cases of tetanus the local lesion is slight, and yet the system is affected by toxin originating from a restricted focus.

Dr. Longhurst had had no intention of taking part in the discussion, but thought there was too great a tendency to localize the disease, of which he believed it quite possible that the origin might be bacterial, but so far, he was sorry to say, none of the speakers had been able to convert him to their view. He believed the disease to be of constitutional origin, and occurring in families prone to rheumatism. Climate has a direct influence, for we do not find the disease making its appearance in hot and dry countries, unless in subjects who had a constitutional tendency to it—for example, in India, during the hot weather; but when the

rainy season set in, the change of condition of the atmosphere developed it. In the mountains it was common enough. That it was due to something in the soil set free by the rain is probable; that this something is a microbe is possible; but statistics are misleading, for they do not take the state of the atmosphere into consideration. What is really wanted is accurate meteorological observation of the disease.

Dr. Cheadle then replied and thanked all for their kind appreciation; he imagined he had been telling them an old story, and was grateful for the gentle criticism. Salicylic acid affects the temperature as it affects the joints in acute rheumatism, rather than neutralizes the poison. The occurrence, simultaneously, of scarlet fever and acute rheumatism in the same house was certainly very suggestive, but he had nothing more to say upon that point. The terms acute rheumatism and rheumatic fever were, he agreed, both open to objection, but what was there as an alternative? The remarkably slow progress of the epidemic in Norway remained unexplained. The cases that derived no benefit from salicylic acid were not ordinary rheumatic cases. That endocarditis should go on developing when other symptoms had disappeared did not disprove the microbic theory of the origin of rheumatic fever. He was quite incapable of dealing with the chemical points advanced by Dr. Haig, but was of the opinion that erythema nodosum is distinctly of rheumatic origin.

Aortic Valvular Disease.—Dr. Alexander Morison read a short paper on "The Treatment of Aortic Valvular Disease," and laid considerable emphasis on the employment of digitalis as a remedial agent. Several members joined briefly in the discussion, all agreeing that digitalis still holds the field.

Rest in the Treatment of Rheumatic Endocarditis.—Dr. R. Caton then read a paper on the arrest of endocarditis in acute rheumatism by the use of complete rest in bed, in the recumbent position (which was never altered even for the purpose of evacuating the bowels), and by a succession of small blisters over the intercostal nerves. In support of his contention he produced statistics of cases treated by him, in which the affection was arrested and in a number of them had entirely disappeared.

Dr. Stephen MacKenzie thought that such a remarkable paper should not be allowed to pass unnoticed, and would certainly give the plan a trial at the first favorable opportunity.

Rheumatism and Gout.—Dr. E. S. Reynolds read a paper on the diagnosis between chronic rheumatism and chronic gout, in which he said that the deformities of the hand due to the former disease were symmetrical, and those to the latter asymmetrical, an opinion that was unchallenged.

Arsenical Multiple Neuritis.—Dr. Alfred Parsons reported a case of arsenical multiple neuritis following the application of a cancer cure, illustrated his remarks by excellent photographs of the unhappy victim of an amateur quack, and was confirmed in his diagnosis by another associate who related the particulars of a very similar case.

Excision of the Breast.—In my own practice I rarely ever apply any ligature whatever in excision of the breast; four or five deep sutures are passed entirely under the wound cavity, and, before closing these, the edges are brought accurately together by a fine continuous suture, no drainage-tube being used; the deep sutures are now firmly closed over lead plates and, usually, bleeding is absolutely stopped; if hemorrhage still continues from any point, an additional deep suture will usually make the wound absolutely dry. The result is that there is practically no bloody serum discharged from the wound, and the original dressings can be left undisturbed for many days.—Ball.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON GENERAL SURGERY.

Stated Meeting, May 13, 1895.

B. Farquhar Curtis, M.D., Chairman.

Thyroidectomy for Exophthalmic Goitre.—Dr. A. J. McCosh presented a girl, twenty years of age, who had been healthy until three years ago, when symptoms began to develop leading up to a well-marked case of exophthalmic goitre. When he first saw her, three months ago, the exophthalmia was well marked, the thyroid was large, the right half being the larger, the voice was hoarse and husky, the heart-beat was 150. She suffered from palpitation and nervousness, and had become very weak and anæmic. In the medical wards she was treated two months by galvanism, arsenic, and thyroid extract, but with no benefit further than what came from rest. She was then transferred to the surgical ward, where Dr. McCosh removed the right half of the thyroid gland. The operation was exceedingly bloody, ligatures alone not being sufficient to control hemorrhage, so that gauze pressure had to be employed. For two weeks after the operation the pulse was very rapid, a part of the time 200, but the protrusion of the eyes diminished noticeably within twelve hours, and at present there was little exophthalmia. The left half of the thyroid which was not removed had decreased to half its former size; the pulse now averaged about 115 or less. She had gained much in weight, and was continuing to improve. After the operation the number of red blood-corpuscles was fifty per cent. less than before, being the greatest diminution which he had ever observed after a bloody operation.

Dr. McCosh said some authors claimed that thyroidectomy was not more dangerous for exophthalmic goitre than for simple goitre, but this was not his opinion. He believed that twenty per cent. of the former class of cases died after operation. Not all of the deaths were due to shock or sepsis, but to a condition attended by symptoms pointing to thyroid poisoning, which had resulted from the manipulations of the surgeon and opening up of vessels. The symptoms were like those produced by over-doses of thyroid extract given for myxœdema—cardiac and respiratory oppression, great prostration, sometimes high temperature, perhaps ending in sudden death. Of cases which survived thyroidectomy, about seventy-five per cent. were cured, of the remaining twenty-five per cent. about half were slightly benefited, the others not at all.

The Chairman, Dr. Curtis, said he had performed thyroidectomy in three cases, and one patient had died, the death having been due, it was thought by Dr. Starr and himself, to absorption of thyroid material. The patient had high temperature, became comatose; in the intervals of coma there was nervous excitement; the urine contained albumin; death at the end of forty-eight hours. The wound was absolutely aseptic, and there had been no inflammatory reaction to account for the rise of temperature. In the other two cases there was also albumin in the urine and rise of temperature after the operation, but the patients recovered.

Suture of Fractured Patella.—Dr. B. B. Gallaudet presented a man in illustration of the treatment of fracture of the patella by open incision and suture, a method which he liked as well as any and had practised in four cases. As there was large swelling of the knee when the patient was first brought to the hospital, he decided to wait a week, meanwhile applying pressure to assist absorption. He then made a transverse incision over the patella, drilled two holes in the upper and lower pieces, which were of equal size, and united them by two silver-wire sutures, closed the wound absolutely, without drainage, and put on a plaster splint. The plaster was removed on the eighteenth day; primary union was found complete. The plaster splint was re-

applied and kept on until the twenty-sixth day, when massage was begun, followed by firm cotton bandage. The patient was discharged, practically cured, two weeks later.

Dr. Gallaudet had been satisfied with this method of treatment, although he was aware that some preferred silk suture, some without drilling holes, some a longitudinal incision, some conservative methods without opening the knee.

Dr. Lilienthal said conservative treatment was not necessarily slow in bringing about a perfect functional result. He had recently shown a patient at the Surgical Society, in which under massage treatment the patient was able to be out of bed by the tenth day, and was discharged cured by the fortieth day. The functional result was perfect, and but for a slight transverse ridge in the line of union, one could not tell there had been a fracture.

Dr. Dawbarn thought there was no difference of opinion among surgeons that the method of treating fracture of the patella described by Dr. Gallaudet was ideal for one who could assure perfect asepsis, but this could not be expected of general practitioners, and for them a conservative method was to be recommended, especially inasmuch as it was likely to give close fibrous union and good functional result. Should it fail, and the patient at the end of a few months should be unable to advance one foot before the other in going upstairs, it would still be time to unite the fractured bone by incision and suture.

Nephrotomy for Stone.—Dr. H. Lilienthal presented a man on whom he had performed nephrotomy for stone. Eight years ago he had had stricture of the urethra in the perineal portion, which had been operated upon by perineal section. Two years and a half ago he had been operated upon for abscess of the kidney, probably pyonephrosis, but as the abscess was very large and had perforated the diaphragm, two ribs were resected and drainage established in that way. He remained well two years and a half, then on February 12th of the present year entered the hospital with high fever, chills, great emaciation, pus in the urine, pain in the left side running downward and forward. No tumor or swelling could be felt. An exploratory incision was made over the left kidney, very firm adhesions due to the former abscess were found. No hard body could be felt in the kidney either by palpation or with the needle, no pus was found; an incision was made down to the pelvis of the organ, but still nothing could be felt. The patient was returned to bed, the high fever and pains continued, and he was expected to die; but three days after the first operation it was decided to explore the organ again without giving anæsthesia, thus having the patient's sensation to guide the exploring finger to the exact seat of pain. Nothing could be felt even then, but on introducing the needle he fancied it produced a little friction, and cutting down on this spot a small stone was found and removed. The patient then went on to recovery. Had he been deprived of the patient's guidance through his sense of pain to the exact location of the stone, as he must have been had he given an anæsthetic, the stone would not have been found and the patient would have died.

Resection of the Buccal Nerve for Neuralgia.—Dr. E. Eliot, Jr., presented a man on whom he had resected about an inch of the buccal branch of the fifth pair on the left side of the face for the relief of periodic pain of seven years' duration, located in the face just over the bicuspid teeth. Zukerkendel's operation was performed with slight modification. The parts supplied by this branch remained absolutely anæsthetic a few days. Sensation was now returning, but there had been no pain. It was not improbable, however, that this would recur in the course of time.

Repair After Bone-flap Operation on the Skull.—Dr. George Woolsey read a brief paper, describing a case in which a bone-flap was removed from the skull for the relief of convulsive and mental symptoms. The boy had had convulsions, and when he regained consciousness there was paralysis of the right side. A year later he could walk well, but had little use of the right hand, and began to have epileptic seizures which increased the next five years. He showed more religious feeling than intelligence. The epileptiform seizures were sometimes limited to the left side, sometimes were general. A horseshoe incision was made over the motor region on the left side, exposing the dura, about two inches and a quarter in diameter. The skull in this region was an inch thick. The membranes were not adherent. The aspirating needle was introduced and brought out fluid which seemed to be cerebro-spinal, from the lateral ventricle rather than from an independent cyst. Dr. Woolsey then closed the wound, suturing the dura, the pericranium, and scalp in three different layers. The boy lived a year and eight months, and was improved a part of the time, but gradually grew worse and died. Dr. Fisher, who had referred the case to him, viewed the autopsy and stated that it was a case of parencephaly, the skull in the motor region being an inch in thickness; the entire left hemisphere much atrophied, the space being taken by a cyst which was continuous with the lateral ventricle; the nerve-tracts below had also undergone degeneration; the left lobe of the cerebellum was also smaller than its fellow.

The points of interest in connection with the case were: 1, By bevelling the chisel only on the inner surface the blows of the mallet were slanting, and caused less concussion of the brain than where the chisel was ground on both surfaces; 2, a number of temporary overlapping sutures through the scalp *en masse* prevented hemorrhage; 3, the method of operating was shown to be applicable even where the skull was enormously thickened; 4, that the inner flap might heal promptly, without adhesions to parts beneath, with smooth inner surface; 5, that the dura, after incision and suture, with use of drainage through the lateral ventricle passing through the suture for two or three days, might heal without adhesion to either bone or pia.

Dr. Dawbarn could not imagine a more successful plan for the prevention of hemorrhage from the scalp wound than that suggested by Dr. Keen, of tying a rubber tube around the head. He had used it many times, and with the result of securing an absolutely dry wound. There were two objections to chiselling the bone, namely, danger of the chisel slipping, and of producing concussion of the brain. He thought the chain-saw, operated by electricity or other motor, devised by an Ohio doctor, was going to prove very useful in bone surgery.

Dr. E. D. Fisher said that, before Dr. Woolsey operated, he thought this boy's condition was probably due to an inflammation starting at the time of the commencement of the fits, but after the operation it was shown that there was parencephaly, and this had probably originated in intra-uterine life; since in parencephaly there was loss of brain substance, one could not expect to accomplish much by an operation. He had not seen concussion from the use of the chisel.

Dr. Woolsey said the saws which he had seen used had not operated satisfactorily. The Esmarch bandage around the head had, according to his observation, been more in the way than it had proven useful in controlling hemorrhage.

The Use of Torsion Instead of Ligatures.—Dr. John F. Erdmann read a brief paper on this subject, basing it upon the use of torsion in over one hundred cases operated upon at the City Hospital. At the present day, he said, we want primary union, and knowing how difficult it was to keep ligatures sterile, he resorted to torsion as a means of checking hemorrhage, for by its use we could dispose of ligatures which acted as foreign bodies, which were apt to excite irritation, which

were apt not to be thoroughly aseptic or to become infected by our hands, and also avoid the possibility of hemorrhage by slipping of the knot. Disposing of these conditions, primary union was more likely to attend our efforts. The possibility of secondary hemorrhage after torsion was very slight, much less, he thought, than after ligation. A hæmatoma had occurred in only one of his 105 cases, and then was due to the patient displacing the dressing. Only a compress was required to stop the bleeding.

Torsion was limited or unlimited. By limited torsion was meant twisting of the vessel below a point at which it was held by forceps, while by unlimited torsion was meant simply twisting the end of the vessel without grasping it above. From four to eight turns were made. Care should be taken to grasp the vessel so as to include its entire lumen. As a result of torsion the inner and middle coats of the artery were ruptured and retraction took place, forming a valve-like occlusion against the exit of blood. Dr. Erdmann said he had not had opportunity to apply torsion to so large arteries as the femoral and brachial, but that Thomas Bryant and others used it on the femoral as well as on smaller vessels.

The Chairman, Dr. Curtis, remarked that by some the fact had been overlooked that by torsion one could get rid of ligature material in the wound. This was very important when we were in doubt as to the aseptic condition of our ligature material. He had seen torsion applied where ligation had to be resorted to afterward, but he thought the fault lay in the operator, not in the method.

Dr. Dawbarn doubted whether there was a surgeon in New York who, if about to be operated upon, would consent to torsion being applied to his femoral instead of ligation. Torsion might do for smaller vessels.

Unusual Deformity of the Coccyx.—Dr. Royal Whitman presented a small boy who had been brought to the hospital because of pain on sitting. Examination showed an unusual congenital deformity of the coccyx, the bone being movable and projecting backward, the usual direction in such cases being forward.

Correspondence.

APPARENT HYPERTHERMIA.

To the Editor of the Medical Record.

Sir: In the Medical Record of July 27, 1895, page 127, in a paragraph headed "The Value of a Good Name," after mentioning the comment of the *Berliner klinische Wochenschrift*, that if Dr. Jacobi's name was not attached one would not believe in the statement that he had had a patient with a temperature of 65° C., and after mentioning the statement in the same journal that I had reported another case of 77° C., or 171° F., you say: "Professor Welch has also a good name, but it would not stand many more degrees centigrade."

I desire to lift some forty degrees centigrade off from this burden on my reputation. I am not responsible for the report of the case of 171° F. It was reported by Dr. Galbraith, of Omaha, in an article entitled "A Remarkable Case," and published in the *Journal of the American Medical Association*, March 31, 1891. In the discussion at the last meeting of the Association of American Physicians, following the report of Dr. Jacobi's case, I referred to Dr. Galbraith's case as an even more remarkable one.

The chief interest to me in the latter case was less the extraordinary height of the temperature than the entire good faith with which Dr. Galbraith, one of the most experienced and best known surgeons in Omaha, reported the case, and the apparent thoroughness of the tests to which he subjected the patient. When called to see the patient in consultation he at first declined, but later went in an attitude of complete scepticism and of confident belief in some mode of deception practised by the patient. He described one test which he made in the following words: "The patient was placed in a chair, all clothing removed, and a careful examination was made of her mouth and axillary region, every possible precaution taken in order to prevent any deception, and holding the end of the thermometer so that it could not be tipped in any way, we again proceeded to take her temperature: but, gentlemen, the result was the same, the thermometer under the axilla registered 137° F., while that under the tongue registered 131° F." His personal examination made a complete convert of Dr. Galbraith. Especially constructed and carefully tested thermometers were used. There were no symptoms indicative of high temperature.

In my comments upon this case and that of Dr. Jacobi at the meeting of the Association, I used the following words (stenographer's report): "So far as one can judge from the description of Dr. Galbraith's case, and the same is true of Dr. Jacobi's case, there was no apparent mode of deception. Still, Dr. Jacobi must pardon me, if, with the greatest respect for his skill as an observer, I express complete scepticism as to the trustworthiness of these observations. I do not undertake to explain in what way deception was practised, but there is no doubt in my mind that there was deception. Such temperatures as those recorded in Dr. Galbraith's and Dr. Jacobi's cases are far above the temperature of heat rigor of mammalian muscle, and are destructive of the life of animal cells. They could not be present even in the integument alone, for any length of time, without leaving behind manifest lesions where they existed. I consider them to be physical impossibilities under the conditions described."

When I made the preceding remarks I was not aware that Dr. Galbraith's case had already been thoroughly discredited by subsequent developments. A physician, Dr. Bridges, who happened to be present when I was speaking, immediately afterward told me that he had been an interne in a hospital when this patient was detected in attempts at malingering. Those who are interested in the remarkable performances of this versatile malingerer will find them narrated in articles by Dr. J. E. Summers, Jr., and by Dr. C. T. Poe, in the *Omaha Clinic*, September, 1891, and February, 1892. I have seen in the Army Medical Museum, in Washington, specimens of the bones sent to Dr. Billings, of which the woman passed per vaginam over one thousand, and which were supposed to come from a macerated fœtus in the abdomen. These bones were pronounced to be bones from fowls, probably chickens, and other animals. None of them were from "any organism developed in the human female." I am not aware that the precise method of deception practised upon Dr. Galbraith has been explained, but Dr. Poe detected the patient once in the old-fashioned trick of heating the thermometer by a hot bottle in the bed. It may be mentioned that the woman had attended a course of lectures in the Woman's Medical College of Chicago.

Yours respectfully,

William H. Welch, M.D.

Baltimore, August 9, 1895.

Prostatic Disease.—About the earliest symptom is an increased frequency of urination, especially at night. This symptom very often precedes any enlargement that can be discovered either by rectal examination or by the use of the catheter.—Keen.

Ligation of the Stump-end.—I can see no sense in ligating the stump-end at all, if it is going to be inverted, any more than I should think of tying a string around a wound in a gut before inverting its edges and using Lembert sutures. The analogy is perfect.—Dawbarn.

THE QUESTION OF AN INTERNATIONAL LANGUAGE.

To the Editor of the Medical Record.

Sir: The agitation for Greek as the international scientific language, by Dr. Achilles Rose, has found many responses. While some are in accord with his views, all agree that since scientific works are no longer written in Latin, a means of common intercommunication is manifestly needed.

The claims of the opponents to Greek are too evident to require discussion. Yet it may not be amiss to call attention to the letter of Dr. George W. Smith, of Chicago, in the Medical Record of August 3, 1895, in which he shows some of the difficulties which present in translation into Greek. But, like many others, he politely omits mention of the impediment to the acquisition of Greek in its written and printed characters. The adjective "politely" is here used advisedly, for Dr. Smith premises that everyone remembers more than the "Alfred, beat her, damn her, belt her," which was more or less successfully hammered into him. Truth is that very few physicians of over twenty years' practical experience can spell the simplest Greek word. In face of this fact, how many could take time from their necessary daily medical studies to learn Greek?

Spanish, on the other-hand, offers *inter alia* the following attractions as an international language: 1. Today over eighty million people speak Spanish. Their scientific publications are numerous, and many among them are of a really superior character. 2. Spanish is written and printed in Latin characters. 3. The Spanish alphabet is unchangeable; no matter how a letter is placed, its pronunciation does not vary. 4. The language is so euphonious that its acquisition is a diversion instead of a task. 5. Spanish spelling is purely phonetic. 6. The learner has but three letters to acquire. 7. The grammar is exceptionally free from irregularities.

To demonstrate how easy of acquisition the language is, and how readily it lends itself to scientific expression, the following is presented without translation, in confidence that no one can fail to understand its meaning:

"La gonorrea es una enfermedád contagiosa que depende de un microbio especifico, descubierto por Neisser y titulado gonococco. Su tratamiento moderno es por inyecciones intra-vesicales de permanganato de potasio."

How many, if the above were presented in Greek, could see anything in it but several lines of hieroglyphs? It is by no means offered as an example of classical Spanish, but as the effort of a mere tyro, who without more than mediocre intelligence and no special linguistic ability, learned enough Spanish in six weeks to no longer require an interpreter.

Ferd. C. Valentine, M.D.
242 West Forty-third Street, New York.

To the Editor of the Medical Record.

Sir: Although you have answered Dr. George W. Smith's letter in your issue for August 3d, "Modern Greek as an International Medical Language," I beg leave to say a few additional words.

The living Greek is a highly developed language. Without much difficulty, every thought expressed in a foreign idiom can be translated into living Greek. We need only read the daily papers published in Greek at this day to convince ourselves of this fact; or we may take for illustration some of the innumerable words which from all languages have been translated into Greek. Moreover, the best contradiction of Dr. Smith's reproach is the Greek medical journal "Γαληνος," which is almost exclusively composed of translations from English, German, French, and Italian medical literature.

Germans are amused or annoyed, according to individual disposition, in reading notices in our railroad depots, saying in monstrous German that smoking is prohibited. Judging from these notices, the German language must be miserably poor and awkward, not even capable of translation of the words "Smoking in the cars is forbidden."

As to the correspondent who wrote upon Latin in a recent issue, I would say that his views are not new, for the Principal of the University of Louvain, in the "Vicar of Wakefield," is made to say: "You see me, young man; I never learned Greek, and I don't find I ever missed it. I have had a doctor's cap and gown without Greek; I have 10,000 florins a year without Greek; I eat heartily without Greek; and in short, as I don't know Greek, I don't believe there is any good in it."

Yours,

A. Rose, M.D.
356 East Fifteenth Street.

To the Editor of the Medical Record.

Sir: "Latin as She is Wrote and Spoke" is the headline of a letter from Dr. H. L. Waldo, of Troy, N. Y., in your issue of August 10th. The doctor deals with his subject in a comic, serio-comic, serious, half-satirical manner, which leaves the reader somewhat in doubt as to his early classical education.

We hope we do not flatter that early training, however, when we take it for granted that he could once read Pindar, quote freely from Horace, and readily unravel the intricacies of Æschylus and Sophocles, but now, like most of us, has grown a bit rusty. Seeing German freely quoted, medical articles displaying great erudition with their multitude of German foot-note references, his heart has been won by the Teuton. Overwhelmed with the mass of German literature, thrashing over and over theories in a spirit of mysticism, he hurls into the background his Virgil and his Homer, and frantically calls for the "Vaporings of Goethe and Schiller, the pseudo-science of Virchow and Ziemssen."

He is serious when he requests the Medical Record to inform him what has been printed, in either Greek or Latin, during the past five hundred years that will pay the physician of to-day to read, if it were printed in his mother-tongue. Again he lays bare his innermost thoughts on the subject when he asks us to remember that our profession is a practical profession. This practical chain of reasoning of the doctor will appeal to many of your readers. No time for dead languages. There are families to keep, babies to feed. No time to unravel the etymological meaning of oculist, aurist, rhinologist, dermatologist, etc. It is enough for us understandingly to call these Æsculapian disciples eyemen, earmen, nosemen, skinmen. However, the advanced medical colleges are demanding from their students some classical education, and it is fast becoming not easy for the machine-shop or grocer boy to obtain his license. The standard is being elevated. It may not be expected from "we busy old fellows," long in the harness, to take any time from the babies and delve into Greek and Latin roots. Those of us who have lived without knowing when and where to use *ferrum* or *ferri*, *rheum* or *rhei*, may remain happy if we do not know the wealth of knowledge pertaining to our profession buried in the classics. In blissful ignorance we may be content to remain Philistines; content to prescribe eyewashes, injections, blisters, and pills, practising on in the same happy frame of mind with that type of day-laborer who returns at night, eats his dinner, drinks his beer, smokes his clay pipe, and goes to bed. To the writer of the article it may be parenthetically remarked, that the physician who unintelligently writes *ferram*, *ferri*, or *ferra*, *aquam* or *aqua*, for iron

and water, does not trifle with the ending any more than he would trifle with the butt-end of a mule. He is content with *fer.* and *ag.* In other words he adopts the trick of the bad speller, when in doubt whether to use i or e, rounds his i, dots his e, and plays it double. The "busy old fellow" is a great abbreviator, and who can know the depth of his knowledge of declensional endings? In one breath the doctor gasps, "What's the use?" while in the next he says, "A large percentage of the technical terms employed in medicine are of Latin or Greek origin." This leads me to ask if he does not agree with the editorial view expressed in the MEDICAL RECORD, to which he refers, "It will not take a great deal of scholarship to correct the general defects of classical learning, and as Latin has become attached to medical literature and nomenclature beyond possibility of divulsion, we suggest that medical students be drilled a little in the mother-tongue." This will apply equally to Greek, which to us at the present time appears of even greater value than Latin, as we watch the newly-coined medical words appearing from day to day, rising, as Barnum would express it, Sphinx-like from the ashes of the Attics.

Yes, Latin and Greek are with us to stay. The new physician is fast being compelled to study them; the "busy old fellow," bearing in mind that Cato learned Greek at eighty, if possessed of any linguistic bump at all, will not find it difficult to acquire enough to make him proud to have lived and gotten one peep into the Promised Land, and see his science unfold itself before him, as he in his practical moments never dared to dream. We may make this good by calling attention to the fact that in the "Beginners' Greek Book" by White appear three hundred words in the first twenty-five lessons. Among these three hundred words, there are about one hundred we use constantly; many of them well-known medical terms. Here are a few:

μικρός	little, small.
κεφαλή	head (micro-cephalus).
ζώνη	girdle (zona or shingles).
στενός	narrow.
ἄνθρωπος	man (anthropology).
λόγος	discourse (all the 'ologies).
ἵππος	horse } hippopotamus.
ποταμός	river }
στρεπτός	necklace.
σώζω	save.

Note here the practical turn made by the business sharp in tacking to the last the Greek word for tooth, and giving us the world-wide advertised dentifrice, Sozodont.

I need not continue this, but repeat that nearly one hundred common words appear in the three hundred words occurring in the first twenty-five lessons of a "Beginners' Greek Book." This means five weeks, one hour daily recitation, for the school-boy.

Does it not suggest the saving of time for the busy practitioner, did he, along with his knives and his scissors, his cumbersome electrical plant, his desk overcrowded with advertisements of headache powders, possess a small Greek and Latin armamentarium? Does he not see how much less the young men and maidens would fool away their time in the laboratories with culture-tubes, etc., did they enter those laboratories with even a limited classical education? They would not stagger under words like streptococcus. Their Greek would at once suggest cocci arranged like a necklace, *streptos* being the Greek for the latter.

Medical education is in the ascendancy, and Greek and Latin must remain invaluable since, from the standpoint of brevity alone, they will remain in use for scientific names.

This wave, starting in the larger medical centres, will surely extend to the surrounding country, and in time reach the suburban towns of East Chatham, Chatham Four Corners, Lansingburg, and Troy.

GEO. R. ELLIOTT, M.D.
48 EAST TWENTY-SIXTH STREET.

PROSTATITIS.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: Since my letter in the MEDICAL RECORD appeared, many private letters from various parts of our continent have been sent here, asking further information in regard to the treatment I proposed. The one word sterilization of the testicle is in my experience the embodiment of success; the moment semen ceases to be developed and spermatozoa no longer manifest themselves, recovery commences.

Any form of injection that will accomplish these ends will, in my opinion, succeed; the body of the testicle should alone be pierced by the needle. I use cocaine because it is painless; because there is no soreness afterward, and the patient is not incapacitated for business; but I presume cold water would serve the same purpose.

I use suppositories made of cocoa butter: 1 grain cocaine, 5 drops extract belladonna, and 5 drops extract henbane—one of these pressed into the bowel every other night.

Where there is a constant desire to urinate I use 1 ounce of hot water 112° to 120° F., 3 grains cocaine, and inject slowly into the bladder, the patient lying on his back in a horizontal position.

I have had remarkable success with this treatment, and am of opinion that castration is wholly unwarranted.

My treatment neither affects sexual desire nor prevents the act of coition. It does wholly prevent reproduction, and would, I think, be a good plan to adopt with noted and hereditary criminals.

Yours,
S. E. MCCULLY, M.D.

TORONTO, CANADA.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending August 10, 1895.

	Cases.	Deaths.
Tuberculosis	53	110
Typhoid fever	19	9
Scarlet fever	30	2
Cerebro-spinal meningitis	1	5
Measles	99	10
Diphtheria	124	23

Penalty for Circulating False Reports.—There is a law in Florida which provides that "any person or persons who shall falsely or maliciously disseminate or spread rumors or reports concerning the existence of any infectious or contagious disease shall be guilty of a misdemeanor, and, upon conviction, shall be punished by a fine in a sum of not less than $100 nor more than $1,000, or be imprisoned in the county jail for not less than three nor more than six months."

The Cost of Typhoid Fever.—Dr. Munro, an English medical health officer, has recently computed the cost of an epidemic of typhoid fever occurring in his district of Mid-Renfrewshire. There were 859 cases, 74 of which were fatal. The average cost of hospital treatment was about $45, on which figure Dr. Munro puts the average cost of treatment of home and hospital cases at $25. He estimates the total amount of wages lost to the patients at about $16,000. The cost of funerals is estimated at $25 each, and the value of a human life a little less than $800 per head. The total pecuniary cost of the epidemic was accordingly almost exactly $125 for each case.

A CURIOUS CASE OF APPENDICITIS; WITH A DISCUSSION OF CERTAIN POINTS IN OPERATIVE TECHNIQUE.[1]

BY ROBERT H. M. DAWBARN, M.D.,

PROFESSOR OF OPERATIVE SURGERY AND SURGICAL ANATOMY IN THE NEW YORK POLYCLINIC SCHOOL AND HOSPITAL.

THE following case of appendicitis presents an unusual number of points of interest in itself. For this reason, and because it will serve as a text for a brief discussion of a few details in operative technique, it has been selected as the subject for to-night's paper.

About eleven o'clock on the night of January 16, 1895, I was called in to see Theodore Van B——, a child eleven years of age. He had then felt moderate pains all day, with some tenderness in the appendicular region, and had been kept in bed by his mother, although seemingly not very seriously ill. He looked up at me brightly and cheerfully at the time of my call. His temperature was one degree above normal; pulse, 120; respiration, 26. The bowels had been moved both that and the preceding day, by a saline. Some anorexia was noted. No tumor could be felt, but a slight degree of rigidity of the right half of the abdominal wall, as compared with the left half. The right thigh was drawn up, and added pain in the abdomen resulted from a gentle attempt to extend this limb.

I have been led to feel that when the symptoms indicate appendicitis, the combination of a rapid pulse and respiration, going with a temperature normal, or nearly so, points to the necessity for prompt operation. Here, however, as the child seemed so bright and cheerful, showing no constitutional evidences of septic absorption, I thought I might safely wait from the time of this my first visit, at nearly midnight, until morning. Before leaving the house orders were given to prepare a room for the purpose; also to fill a wash-boiler with normal salt solution (heaped teaspoonful to quart of water) and boil it, prior to the morning visit.

That night I was awakened before daybreak with the news that the little patient had just been seized with a severe chill. Reflecting on Dr. Fowler's remark—that in three hundred cases of appendicitis he had only seen two in which a chill ushered in the symptoms, and in both of these the appendix was found gangrenous—I anticipated a similar condition here, although the chill did not absolutely begin the case. And this assumption proved to be true.

As soon as assistants could be gotten together we operated, in the early morning. These gentlemen were Drs. William J. Kress and Richard A. Barr. Upon our arrival the patient's condition was deplorable, and in striking contrast to that of the midnight visit. The pulse was now running and thready, at about 140 per minute; respiration, 40; temperature, about 99° F. The tenderness had spread over the whole abdomen, though still worse on the right. The little fellow was covered with a cold sweat, and his face showed anxiety.

The prognosis seemed to be of the worst, and perhaps hardly justified operating. However, the parents chose the only course offering the least hope, and we went ahead with ether anæsthesia. Upon opening the abdomen there was a prompt escape of fluid fæces mingled with pus, dark and very malodorous. This seemed to bathe the bowels everywhere, most of it being found in the pelvis. The estimated amount removed in cleansing was from four to six ounces. The bowels were distended, dark red or purple, and distinctly inflamed. Upon searching for the appendix, a curious and beautiful instance was made manifest of Nature's attempts to protect herself against threatened bowel-perforations. That corner of the great omentum which lay nearest had wrapped itself completely around the diseased appendix—just as a woman might wrap the corner of her apron around a sore finger.

From beneath this attempted protection the fluid fæces could be seen welling up; showing that the effort had not quite succeeded. The omentum in this region was greatly congested and stiffened, and was swollen to several times its normal thickness in a child. Upon unrolling this corner of the great apron, the appendix lay exposed, gangrenous for its distal three-fourths, and perforated at two or three points. Where the partly healthy joined the dead portion was a round distention of its wall, evidently old, and covered with smooth peritoneum; and this cavity was filled with a round and hard body the size of a large pea. This sacculation is quite clearly shown in the specimen to-night, which has been sewn together where it had been split lengthwise, and then filled with plaster-of-Paris.

Strangely enough, although this sac in the wall of the appendix is evidently of old standing, yet the parents insist that no tenderness nor pain whatsoever had been complained of prior to the day before the operation. The hard body resembled a stone in density, not yielding at all to the finger-nail. Examination later on, however, showed it to be scybalous. The appendix was now removed by a technique which I have used almost exclusively for several years past and will discuss later on.

Next, the wound was freely enlarged at both ends, until seven inches in length; and then every foot of the bowels capable of removal was quickly withdrawn so as to lie upon the skin of the abdomen. Now, the normal salt solution, as hot as the hand would bear, was poured from a pitcher upon the bowels, which were gently moved in all directions, to favor thoroughness of cleansing. Pitcherful after pitcherful was used, and then the empty cavity in which the intestines had lain was as freely flushed the inserted hand aiding the washing continually, the fingers searching out all recesses, until the water returned absolutely colorless. Without exaggeration, almost an entire wash-boilerful of hot normal salt solution was used in this way. The bowels were replaced with some difficulty, as they were distended with gas when first exposed. A shorter skin incision would have rendered their return almost impossible, save by a most serious degree of rough handling. Next, the infected and swollen portion of the omentum, as referred to heretofore, was ligated in sections and amputated. In this way about one-third of the great apron was sacrificed. The wound was now closed as to its ends with silkworm gut sutures, and all the rest of it packed with a mass of sterile gauze, strips of which ran like the spread fingers of a hand in as

[1] Read, in major part, at a meeting of the New York Surgical Society, held April 10, 1895.

many different directions among the bowels, and particularly into the pelvis.

The little patient's condition at this time was such that it was feared he would die on the table. Hot saline infusion, intra-venous, was employed, nearly a quart being used with great benefit; also whiskey and hot water by enema and strychnine by needle: and finally he reacted well.

As to the subsequent history, only those portions which are of unusual interest will be recorded here, and these as briefly as may be.

First, the extreme difficulty of moving the semi-paralyzed bowels. This it was thought best to attempt on the second day. Large doses of salines were given by mouth hourly, and, later on, castor-oil; stimulant enemata of soap, of glycerine, with salines, with ox-gall, with turpentine, were used at intervals—and all without effect for a long time. After between one and two days of effort, success was achieved in this direction.

As showing the extremely ichorous character of the fluids which came in contact with the raw surfaces of the incision in the belly wall during the operation, it is to be noted that the entire thickness of the wound, on both sides, sloughed, presenting a gray, offensive surface on the third and fourth day, and compelling the removal of the few sutures at the ends. In the treatment of this sloughing surface sterile gauze soaked in oil of turpentine was freely employed and changed daily, the skin being thickly dusted with compound talcum or bismuth subnitrate, to avoid turpentine blistering. This treatment was not much complained of, and was ideal in its results. Indeed, in foul and sloughy wounds, everywhere, the writer knows of no plan of equal value with this, which he first saw suggested many years ago by Dr. Banks, the Liverpool surgeon.

Since then he has found that from time immemorial it has been standard treatment for foul wounds among the people of the pine-woods districts of this country.

On January 22d, six days after the operation, there developed with rapidity an acute and severe degree of parotitis on the child's right, causing him much suffering. At this time the sloughs were not yet gone from the wound, and the temperature was 100° to 101° F. Under an ice-bag the pain and swelling diminished, and two days later had in some measure subsided, when the same complication supervened, this time involving his left parotid gland. This again took a similar course under the same cold treatment.

I had feared the worst when this sympton developed. It is, I believe, generally regarded as of very grave prognosis; not of course *per se*, but as indicating a condition of profound sepsis. It will be remembered that a few years ago one of the surgeons to the New York Woman's Hospital published an article pointing out its extreme fatality.

The next complication presented by this little sufferer was about this same time in its inception. The temperature after the double parotitis did not drop to normal, but gradually and irregularly rose, covering about a week, until upon February 4th it had reached 103½°. During this week he had several slight rigors with sweating, at irregular intervals; and his strength fell away alarmingly, in spite of strychnine, stimulants, and concentrated foods used freely. Quinine had no effect upon this fever, and I felt certain that there must be concealed somewhere in his abdomen a pocket of pus which was poisoning him. But exactly where I could not determine, either by subjective or objective means. During the last few days of this period the wound looked quite normal and was covered, including the adherent bowels which formed its bottom, with healthy granulation-tissue. The temperature alone prevented secondary suturing, or other means of closing this great gap. I hoped that the suspected abscess might point and break in this direction if the wound were kept open.

Upon February 3d it was determined to use a coarse aspirating needle in various directions through the thick bed of granulations at the bottom of the wound. This was done, but no pus was found. It was thought that the little patient was too weak to bear a fresh laparotomy, or even to endure the rough handling involved in tearing apart the firmly adherent bowels beneath and about the wound.

Upon the day following this aspirating, Dr. A. G. Gerster was called in consultation. He made a careful examination and confirmed my diagnosis of an abscess-cavity concealed somewhere, and poisoning our patient; but could not localize it; and he, too, advised against operation, for the reasons named.

Within a few hours after Dr. Gerster's visit, the child solved this mystery for himself, by discharging this abscess through some unknown point into his bowel, and thence per anum. This movement was large and fluid and dark, and was so peculiarly atrocious in odor as to be almost overpowering. The mother told me that, in spite of the wintry weather, every window and door in the flat had to be opened for exit of the smell. Within an hour after this the temperature had dropped nearly two degrees; and it quickly fell to normal.

A few days later the fever and all these symptoms of poisoning again returned, but to a lesser degree. A second and smaller offensive movement ended them, and since then they have not recurred, nor has anything further happened to interrupt convalescence. Daily, under saline laxatives, the bowels were made to move freely during the septic periods mentioned. Each time, a soft and normal movement preceded the very foul ones by a few hours, so that the latter could not have been due to constipation with retention and decomposition of fæces.

It would seem quite plain that in this case an abscess beginning in some peritoneal recess such as the fossa of Treitz, or perchance the fossa sub-sigmoidea, and walled in by matted intestines, had at length softened and penetrated a contiguous loop of bowel.

The patient is now in good health and free from pain. His wound is solidly healed, and has contracted one and a half inch at each end; it is now measuring four inches along the scar.

I. First, as to the incision. As a general thing, Dr. McBurney's plan of splitting the abdominal muscles so that the split external oblique makes nearly a right angle with the split internal oblique and transversalis, would seem a distinct gain, and for the reasons which Dr. McBurney has pointed out. But in a case such as this, and indeed in any case where one has reason to expect pus, it would seem wiser, as he has himself stated, to make the more usual cœliotomy incision. The McBurney plan compels a free dissection and fully double as much raw surface to absorb poison.

II. Regarding the recognition of peritoneum as distinguished from transversalis fascia. These membranes cannot always be distinguished by a differing appearance. I have often seen transversalis fascia that did not look fibrillated and was just as shining as the peritoneum. Possibly it may be worth while, for others than the members of this Society, to refer to a valuable point which many years ago I obtained from Dr. McBurney, and have never seen in print, namely, that after cutting the deepest muscle, its cut edge be lifted and its deep surface examined. If, now, that surface be found bare, then the transversalis fascia has not yet been cut. But if that under surface of the deepest muscle be found covered with a fascia, however thin, that is the transversalis fascia, which has already been cut, and then the next membrane attacked will of course be the peritoneum.

III. In common with certain other surgeons, the writer is now inclined to advocate a double incision in every appendix case with a tumor.

Through the first and very short incision, at or near

the middle line, the forefinger is introduced into the peritoneal cavity, and by it the tumor is felt. If adhesions separate the general peritoneal cavity from the pus-cavity, then this finger serves as the best possible guide, while the second cut is being made, to enable us by that second cut to enter that pus-cavity without at any point through inadvertence entering and contaminating the general peritoneal cavity.

IV. Suppose, in an appendicitis case with a tumor, we have made our first and short cut, introduced the finger, and have found it capable of sweeping all over the front of that tumor; that, in other words, there is no blocking off of that tumor from the general peritoneal cavity, at least at the front. Shall we now, after making our second incision, which exposes the tumor, attack it at this sitting, open, wipe out the pus, and drain? Or shall we pack gauze around the periphery of the tumor and wait, before cutting into that pus, a day or so for the rapid adhesions which will in that time make a protecting barrier, closing out absolutely the general peritoneal cavity?

As Dr. Wyeth has so strongly advocated, I think the latter plan by far the preferable, because the safer. But on page 159 of his recent work upon appendicitis, Dr. Fowler takes the opposite course, and opens into the pus at once.

The plan in two stages is directly in line with the tehnique which has, elsewhere in the abdomen, made a wonderful change in the direction of lowered mortality; as, for example, doing inguinal colotomy in two steps a day apart, instead of one, as formerly. Of course, in the appendicitis contingency just discussed, if the localized abscess were tense, threatening to burst, it would be wise to aspirate, to avoid this occurrence, and then pack gauze about as aforesaid.

V. Regarding the position to be assumed by the patient. The writer is not an advocate of Trendelenburg's posture in this operation, either in purulent or non-purulent cases.

As to the former class, Dr. Fowler, in his work (p. 152 *et seq.*), points out the objection (when there is a tumor, or any other reason for assuming that septic fluid will be encountered) that in such cases the Trendelenburg position "has the disadvantage of favoring the passage of the pus to the upper portion of the peritoneal cavity; and, at the same time, of preventing the rapid turning of the patient upon his right side, in order to obtain the assistance of gravity in preventing the infection of the peritoneal cavity."

As to the latter class—the non-purulent cases—I would say that here again the horizontal dorsal position is the best; for another reason, namely, that it enables one, more readily than by the Trendelenburg posture, to overcome a common annoyance, that caused by the small intestines crowding into the field of operation and persistently hiding the deeper appendix in the most exasperating way.

In such a case, the plan I suggested here several years ago gives prompt relief. This is to roll the patient over, so that the right side is uppermost. Now, with a stout retractor, draw the belly-wall, at the cut, forward, *i.e.*, away from the spinal column. Thereby a capacious pocket or pouch is formed, into which the small intestines drop by gravity. The cæcum, having no mesentery, cannot, however, follow the small intestines, and must remain uncovered and where it is desired, namely, directly beneath the cut. This little device alone has many times saved precious minutes of peritoneal exposure. The cæcum being plainly in view, the appendix is now found by following either of its bands down to its ending.

To a lesser degree the Trendelenburg position also removes the intestines from the operative field; but often (and especially when they are at all tympanitic) not so perfectly as in the plan just described, because the liver, right kidney, and hepatic flexure of the colon are near enough to the wound to prevent as large a free space being formed for the bowels to drop into as will be obtained by the writer's method.

VI. *A propos* of the curiously dense, scybalous ball which filled the sacculated side of the appendix, as alluded to in the case recorded here, perhaps it will not be amiss to record another and similar instance, which teaches a lesson.

Last week the writer operated upon a patient of Dr. H. G. Myers, of this city; another little patient with gangrenous appendix. The belly was full of pus mingled with fluid fæces, and the child died of shock and sepsis a few hours later. The curious and instructive point was that we removed from the appendix what seemed to be a date-stone. This was handed about for inspection, and no one questioned its nature. But upon being washed, later on, it softened and crumbled into fæces.

I have seen two similar cases: one in which a "peanut," removed by another doctor, proved to be scybalous, and the other in which an "orange-pit," which was shown me months after the operation, and after dozens of people had accepted its nature without a doubt expressed, under the finger-nail finally revealed itself as hardened fæces.

I question whether a large percentage of supposed offending fruit-seeds may not be of this character. Dr. Fowler and other writers also take this view.

VII. It is with great interest that the writer has noted the wide difference of opinion which exists regarding the proper treatment of the appendix in ordinary non-perforative cases. In this surgical society he has found by casual inquiry three or four plans in use by as many different members with whom he has talked, and of course referring to one and the same kind of appendices. This fact has led to a collection of different plans, by aid of the library. The following methods have all been used and advised by different writers, and comprise (save for minor and unimportant details) all the plans with which the writer is acquainted:

1. Division flush with the cæcum, and the hole so left closed with one, or more commonly two, rows of Lembert sutures.

2. Ligation at junction with cæcum; section; disinfection of stump by dissecting or by scraping away the infected mucous membrane. And finally, attempted sterilizing of stump, either by Paquelin cautery, or else chemically, as by fuming nitric acid, or rubbing with a bichloride of mercury tablet, or applying a drop of pure carbolic acid.

3. This is plan No. 2, plus burial of the stump beneath the peritoneum of the cæcum. This may be done either by (a) simply one or two rows of Lembert suturing, hiding the stump at the bottom of a furrow, or (b) the peritoneum is incised, flaps of it are dissected up, the stump (made up of ligated muscular and mucous coats of the appendix) tucked beneath these flaps, which are then sewn together.

4. Division, leaving a short stump of appendix; which is then disinfected by being cauterized within—the mucous membrane being seared by a slender Paquelin point. Next the stump is ligated, thereby bringing the burned surfaces in contact.

5. Same as method 4, except that a final step is the closure of the peritoneum over the burned and ligated stump, by Lembert sutures, with either (a) or (b) of method 3.

6. Same as method 5, except that ligation is omitted. The divided appendix has its stump seared within; and then the said very short stump is buried beneath the cæcal peritoneum by one or two rows of Lembert sutures.

7. Leaving the divided appendix stump a half-inch long; sewing its mucous coat together at the divided end; then sewing the peritoneal coat together over this; and finally, sometimes sewing the stump so that its end is brought in contact with adjacent peritoneum, as an added protection—either that of the cæcum, or

perhaps that of the divided mesentery of the appendix.

8. Tying and dividing, leaving a half-inch stump. Disinfecting this as heretofore mentioned (in plan 2). Inverting it and sewing the cæcal peritoneum over it by Lembert sutures.

To this last step—concealing the end of the stump under mesenteric or adjacent omental peritoneum—several writers refer.

9. In cases greatly softened by inflammation, so that stitches cut out of the cæcum, or a ligature would cut through the appendicular base, we may apply one or more small, light hæmostatic clamps; divide distally to these, and leave them in place a day or two.

10. Inverting the entire and unopened appendix into the cæcum.

11. Doing nothing to the appendix, if this organ is found so placed, or so bound by adhesions, that considerable violence would be needed in order to free and remove it, or that by freeing it a protecting layer of adhesions against peritoneal infection would be opened up.

12. The plan advocated by the writer.

This last I have employed in every suitable case for several years past. It is as simple as it is effectual and easy of accomplishment. (It has recently been described by a writer in the *International Journal of Surgery*, together with a study of these eleven other methods.) Regarding the question of its novelty, both Dr. McBurney and Dr. Fowler, of this Society, have told me that it is new to them. Dr. Fowler will include it in the new edition of his well-known work upon appendicitis. A recent letter from this gentleman, showing his estimate of the device, is as follows:

"Dear Dr. Dawbarn: In reply to a communication received from you some time ago, would say that I have attempted your procedure in six cases, since you so kindly demonstrated it for me upon the cadaver, at the Polyclinic. In four of these (two of which were recurrent cases operated upon between attacks, the other two being early acute cases) no difficulty was experienced in accomplishing the inversion. In a fifth, after attempting to invert the appendix and failing, I at last succeeded, after shortening the appendix-stump considerably, and destroying the stenosis at its base, by introducing the thermo-cautery, and "boring through," as it were. The sixth case was gangrenous at its base (and hence not applicable). I congratulate you upon this clever and efficient device for disposing of the stump of the appendix. I am

"Yours very sincerely,

"George R. Fowler."

Upon May 29th Dr. Fowler mentioned to me, as a *postscriptum*, four additional cases in which he has used the plan—all easily and successfully. He spoke of it as being the "briefest and best."

Dr. Fowler's assistant, Dr. H. B. Delatour, Visiting Surgeon at the Methodist Episcopal and Norwegian Hospitals, Brooklyn, has just recently written a note saying, "I have used your plan in three cases of acute appendicitis, and in two cases where the appendix was removed during operations on the pelvic organs. It has been entirely satisfactory, and is the best I know of. It has certainly shortened the duration of the operation, too. Even in the acute cases with adhesions, by means of a small, curved needle the purse-string suture, which precedes the inversion, was readily placed."

Dr. Edward L. Williamson has kindly spent a part of several days at the New York Academy of Medicine library, looking over appendix literature, and has not found this plan described. And in further evidence as to priority, I beg to submit the two letters printed at the end of this article. The steps are as follows:

a. A continuous Lembert suture of silk is made to surround the appendix, running like a purse-string or gathering-string in the superficial layers of the cæcum, one-fourth inch from the appendix. This suture is not yet tightened, though the first half of a surgeon's knot is made ready.

b. The appendix is divided, leaving a stump of variable length, but never shorter than a half-inch.

c. This stump is stretched for a moment, as to its calibre, by introducing through it a closed pair of mouse-tooth forceps, into the cæcum, and then gently opening the blades. Thereby any stricture, from swelling or plastic deposit, will be stretched; and the next step made even easier than otherwise.

d. The stump is seized at the extreme of its free end by a similar fine-pointed pair of mouse-tooth forceps; and the stump is promptly invaginated—turned "outside in," as a glove-finger might be. So that when completed the forceps and appendix-end are one-half inch inside the cæcum.

e. The suture is tightened, during which step the forceps are withdrawn. Sometimes it is a help to insert a grooved director or a probe between the open jaws of the forceps, prior to withdrawing the latter, in order to prevent the appendix drawing itself out again with them.

In this, as in so many points of surgical technique, attention to the smallest details is worth while. For instance, as the appendix, the cæcum, and the surgeon's fingers are all wet and slippery, time will be saved by holding the viscera, during invagination, with dry sterile gauze.

Again: During the stretching of the canal alluded to, the cæcum must be pressed between thumb and finger, near the appendicular attachment. Consequently, no fecal contents can jet out during the instant of stretching.

Of course, it is admitted that in a few instances the plan above advised is not feasible. For example, when the appendix is gangrenous from end to end, or has entirely sloughed away. More often, from softening of the cæcal walls, it seems wise to place two rows of the circular purse-string suture, the second lying a quarter of an inch outside the first.

When from inflammatory deposit the cæcal or appendical walls are almost as rigid as a pipe-stem, it is plain that invagination might not be feasible nor closure by a purse-string suture. However, a moderate degree of stiffness of the appendix makes the inversion even easier than otherwise, by keeping the lumen patulous.

The theoretical objection to this plan has been suggested to the writer, that one may have loss of time from bleeding of the divided end, which is not surrounded with the customary ligature. This objection is without basis in fact. The preliminary ligation and division of the mesentery of the appendix cuts off its main blood-supply. Should a vessel of the divided end spurt, I have found nothing to be easier than to control it instantly by torsion.

For the above-detailed technique I would claim that it applies to this region the rules of surgical procedure used elsewhere by all surgeons in wounds of the gut, namely, to invert the edges, and bring peritoneal surfaces in contact.

What would be thought of the surgeon who should treat a wound of the bowel by tying a string around it, leaving infected mucous surfaces tied together? And yet is not this just what many operators do to-day when they ligate the appendix at its base, and cut off? Practically, they have a round hole into a gut, with a string tied about it. And although by scraping and cautery or caustics they try to sterilize the stump beyond the ligature, yet the fact remains that the ligature is still holding two infected mucous surfaces in contact which will not and cannot be made to grow together. Fibrinous exudate over the stump in most cases hides and protects this botch, and being thick prevents a fistula. But there are occasional cases recorded in which, as it seems to the writer, a subsequent small

exit of fæces at the wound has plainly had this for a primal cause.

If, before tying the stump, the mucous membrane be burned away by inserting into the lumen a delicate cautery point—which is a favorite technique of some operators—then, to be sure, those infected mucous surfaces no longer exist; but that surgeon is now bringing two sloughs in contact. And sloughs cannot surely be expected to grow together, being dead tissue. We are depending again upon a providential deposit of thick fibrin over a bad job. Of course, Providence generally obliges us; but why use a bad principle when a good one, and an easier and safer, is at hand?

In criticism of the plan of ligating the stump (or its mucous tunic only), next disinfecting the end by any plan, and then bringing peritoneum over it, by suturing, either with or without first dissecting back a cuff or flaps: Here, whether a fistula results or not depends on whether the peritoneal stitches or the catgut ligature on the buried stump-end give way first. The conception is faulty, because again you have foul mucous surfaces tied together. If, too, there occur a rapid secretion of infective fluid in this hollow stump, that poison lies between what are practically two ligatures; and may burst outwardly, or force itself between the peritoneal stitches, before the catgut on the stump is absorbed.

Whereas, by the plan the writer advocates, drainage is perfect and unopposed into the cæcum, where it ought to go, and the long inverted stump is an added safety against outward leakage, by bringing so much more of peritoneum in contact.

This last point shows the objection to the plan of simply amputating close to the cæcum, and placing one or two rows of Lembert stitches to close the hole. It is surgical and correct in conception, and brings the peritoneal and not the mucous tunics together. But the writer contends that by invaginating a half-inch of the appendix-stump, when this can be done (which is almost always), there is just that distance more of peritoneal surface brought in contact as a safeguard against leakage. To throw this safeguard away deliberately, by cutting the stump short off seems to the writer unwise. Also, the necessity for two rows of Lembert sutures is obviated by the plan advised herein.

Regarding Dr. Edebohl's plan of inverting the entire and unopened appendix, the writer can see no sufficient advantage in doing this in healthy appendices, and in a long appendix it is extremely difficult. In the diseased organ it will generally be found impossible of accomplishment. Severing and stretching the canal for a moment by the plan advocated in this paper are essential, as a rule, in order to invert a stump of more than merely trivial length, because of the plastic and congestive strictures so often present.

VIII. Finally, the writer would say that he attributes the little patient's recovery, whose case has been to-night discussed, mainly to the thoroughness with which flushing of the bowels and peritoneal cavity was performed.

As a rule, wiping away pus or blood or fæces is doubtless much safer than irrigation, provided these fluids be localized. But if diffused, that alters the case. And if we must irrigate, it is certain that withdrawal of the bowels outside, so far as adhesions permit, greatly aids thorough cleansing, both of intestines and of the various peritoneal pouches and recesses.

In a paper published recently (see MEDICAL RECORD, March 30, 1895), Dr. McBurney reports a series of most interesting cases of this kind, treated by irrigation with salt solution and packing, just as this one was. But if Dr. McBurney withdrew the bowels in any of these instances, it was at least not mentioned.

Of course it is plain that there may be some added shock from the procedure, but as absolute thoroughness alone offers the least hope in these desperate cases, the withdrawal seems the lesser evil.

103 WEST SEVENTY-FOURTH STREET, June 25, 1895.

"UNITED STATES NAVAL HOSPITAL,
"PENSACOLA, FLA., April 24, 1895.

"MY DEAR DOCTOR: Your note of April 21st has just reached me and I hasten to reply.

"In regard to the technique as to the treatment of the stump after operation in cases of appendicitis, I have not only a distinct recollection of the plan you suggested, but I have notes made at the time of your demonstrations. It is four years since I first saw you demonstrate the plan, April, 1891, and less than six weeks since I saw you again demonstrate the same method. It strikes me that such a simple method as turning 'outside-in' the stump of the appendix, and tightening a previously arranged purse-string suture, would have occurred to one as a simple and radical method of treating the long stump. If the credit of having established this neat procedure is due to you—and to establish your claim you needs must show that you demonstrated it in 1890 and 1891—I cheerfully state that in April, 1891, I was a member of your Operative Surgery Class in the Polyclinic, and again in February and March, 1895; and in the presence of both classes you showed the method of inverting the long stump and the use of the purse-string suture in the cæcum about the base of the appendix. You ask me to describe the plan you showed in 1891, as I remember it. In my notes, I find that there were four steps in the procedure before tying: 1. A continuous suture of silk around the appendix (Lembert's suture) in the superficial layers of the cæcum; tie first part of surgeon's knot, but do not tighten. 2. Cut the appendix, leaving a stump at least one-half inch long. 3. Stretch calibre of the stump. 4. Seize and invert end of stump by using mouse-toothed forceps. Now tighten the purse-string suture while withdrawing the forceps.

"I trust that this may serve the purpose for which you wish it. I am sure that Dr. Arnold and Dr. Brewer can substantiate what I state. Dr. Arnold is now in China on the Petrel.

"With best wishes, I am
"Cordially yours,
"JAMES SHIRLEY HOPE,
Passed Assistant Surgeon, U. S. Navy.
"TO DR. H. M. DAWBARN."

"UNITED STATES STEAMSHIP PETREL,
ASIATIC STATION, May 24, 1895."

"I wish to be a witness that, in April, 1891, I took a course at the New York Polyclinic in Operative Surgery under Dr. Robert H. M. Dawbarn, the other members of this class being Assistant Surgeon James F. Keeney, U. S. N. (now deceased), Dr. J. S. Hope, at present also a member of the Navy Medical Corps, and Drs. M. M. Brewer, S. B. Jenkins, and J. N. Jackson; that during said course Dr. Dawbarn demonstrated, as the usual technique with him in treating cases of appendicitis, the operation detailed below; and I can be the more certain of the steps involved, because I performed the operation in question upon the cadaver under his directions and made up my notes of it from memory immediately afterward.

"*Steps of Procedure.*—1. After exposure and isolation of the appendix, a continuous Lembert's suture of silk is applied in the superficial layers of the cæcum, so as to surround the head of the appendix at a distance from its insertion of about one-fourth of an inch. Then the first turns of a surgeon's knot are made ready to be tightened. 2. The appendix is to be removed so as to leave a stump of a length of one-half an inch, if its condition will admit of this. 3. The lumen of this stump is stretched by the gentle separation of the blades of a pair of slender forceps inserted through it into the cæcum. 4. The stump, thus freed from plastic adhesions or other contractures, is then to be inverted into the

cæcum by passing the cut end of the appendix-stump into its lumen in the grasp of a pair of slender-jawed, fine-toothed forceps, upon which the purse-string suture is then gently drawn. 5. After the withdrawal of the forceps, this suture is drawn in until the peritoneal surfaces are closely opposed, when it is to be made fast.

"W. F. Arnold, M.D.,
"*Passed Assistant Surgeon, U. S. Navy.*"

REPORT OF INTUBATION CASES.[1]

By FREDERIC M. WARNER, M.D.,

NEW YORK.

VISITING PHYSICIAN TO THE CITY HOSPITAL; CONSULTING PHYSICIAN TO THE FRENCH HOSPITAL, DEPARTMENT OF DISEASES OF CHILDREN.

The increase in favor of the operation of intubation over tracheotomy in this country has been steady and constant. The latter, formidable at best to the lay mind, involving the abhorrent cutting of the tissues and the sight of blood, has in the majority of instances been performed under the greatest disadvantages; scarcely ever permitted until the patient has been beyond chance of recovery. Intubation, on the other hand, when properly explained to the child's guardians, never meets with any opposition, except from the densely ignorant, and it may be done as early in the disease as the operator deems necessary. In Europe, where they have been loath to believe that the genius and perseverance of O'Dwyer have succeeded where Bouchut failed after halting on the brink of discovery, the operation is handicapped by doubts and improperly made instruments. This series of cases that I am going to relate is numerically small, only twenty in number, but in detail full of interest to those to whom this subject appeals.

They were all desperate cases, in my opinion and in the judgment of those who saw them with me. They would have each and all terminated fatally without operation—even if the calomel sublimation treatment, which has modified the prognosis in croup to a considerable extent, had always been employed. Many cases have recovered under this treatment which formerly would have only survived by the aid of operative interference: but again, there are many cases which are not influenced favorably by the inhalation of vaporized calomel, no matter how early in the disease this agent is employed.

Case I.—H. M——, five years of age, male. Membranous exudate on nasal and pharyngeal mucous surface and in larynx; albumin in urine; child had been sick ten days; the larynx had been involved about four days. There was marked supra- and infra-sternal depression, with extreme dyspnœa and lividity of surface. Upon introduction of the No. 3 to 4 tube a piece of false membrane about two inches in length was expelled, to the relief of all the distressing symptoms. The tube remained in the larynx four days, when it was coughed out, and the child made an uninterrupted recovery.

Case II.—H. P——, aged twenty months, female. Extensive membranous deposit upon tonsils and in pharynx and in larynx; extreme dyspnœa. Child had been sick eight days, but the laryngitis had been present only about twenty-four hours. A No. 1 tube was introduced about 9 A.M. and the child did well, breathing easily until about 5 P.M. of the same day, when the temperature commenced to go up rapidly, coincident with the extension of membrane into the lung, and death occurred eighteen hours after introduction of the tube, which was removed post mortem, lumen clear.

Case III.—S——, aged five years, male, had been sick eight days, with twenty-four hours of laryngeal complication. When I saw the child there was considerable membranous deposit in the pharynx, together with a great deal of œdema. A No. 3 to 4 tube which was introduced was coughed out at the end of twenty-four hours. The dyspnœa continuing, the same tube was reinserted and was again coughed out in about twelve hours. Ten hours later, the breathing becoming very difficult, I introduced a No. 5 tube, the next larger size. Three days afterward the child expelled this tube and went on to complete recovery.

Case IV.—R——, aged three, male. The child had been sick about twenty-four hours. Large membranous deposits on tonsils and wall of pharynx, associated with extreme dyspnœa. A No. 2 tube was introduced and the patient did well for four days, when the membrane commenced to extend downward, and in twenty-four hours the child was dead. The tube was removed post mortem.

Case V.—B——, aged four, female. False membrane on tonsils and pharynx. Child had been hoarse about two days. The case was very urgent, the dyspnœa being extreme. A No. 3 to 4 tube was introduced with immediate relief, and the case progressed favorably. At the end of six days the tube was coughed out, and although the child was suffering from the toxic effects of the disease the laryngitis had apparently disappeared. Four days afterward the patient again became croupy, and it was necessary to again insert the tube. Three days afterward, during a paroxysm of coughing, the tube was expelled, but I was obliged to reinsert it in about two hours to relieve the difficulty in breathing. The child died about twelve hours afterward of blood-poisoning.

This is one of the most interesting cases that I have seen, showing, as it does, that life was prolonged about fourteen days by the employment of the operation of intubation.

Case VI.—T——, aged five, female. The child had been sick about three days, dyspnœa having been present twelve hours when I saw it. It was a desperate case; the throat was swollen and a mass of false membrane. The child was livid and apparently lifeless. As a forlorn hope, not that I expected any result, I introduced tube No. 5 and tried artificial respiration, with no effect. I then pulled out the tube by the attached thread, and a little membrane and mucopus came with it. The patient began then to respond to the efforts at artificial respiration. Some whiskey hypodermically helped restore the heart's action and the child coughed out more membrane and muco-pus, and then breathed freely. Ten hours afterward I found the patient cyanotic and almost pulseless. I introduced tube No. 5, through which the patient expelled considerable false membrane. Twelve hours afterward I saw the child breathing easily and in good condition, except that the heart's action was feeble. I cautioned the mother particularly to keep the child lying in bed and not allow it to be agitated or disturbed. One hour afterward the child suddenly sat up in bed, and fell back dead. I removed the tube post mortem and found the lumen clear.

Case VII.—D——, aged two, male. The patient in this case had been suffering from dyspnœa for two days. There was no membrane to be seen in the throat. On introduction of tube No. 2 several large pieces of membrane were forcibly expelled, and the child was left in perfectly comfortable condition, but died sixteen hours afterward, presumably of extension downward of the false membrane.

Case VIII.—M——, aged sixteen months, male. Six weeks previously this patient had an attack of measles, and since that time there had been more or less croupy breathing. Suddenly one morning he was seized with an attack of dyspnœa which became very rapidly more intense. A No. 1 tube was introduced four hours afterward with considerable relief, but the

[1] Read before Section on Pediatrics, New York Academy of Medicine, May 9, 1895.

child died sixteen hours later of extension downward of the membrane.

Case IX.—L. S——, aged five, female. This patient had been suffering from a croupy cough and voice about ten days. Upon insertion of a No. 3 to 4 tube considerable muco-pus and false membrane were expelled, and about fifteen minutes afterward, during an attack of coughing, the child became suddenly livid and gasped for air. I realized that the tube had become occluded with detached membrane, and as in those days I used to cut off the thread as soon as the tube was in place, I could not pull it out. My extractor was in the case on the other side of the room, and rapidity of action was imperative. The child was sitting on the lap of the nurse directly in front of me. With the fingers of my left hand I forced up the larynx externally, and I saw easily the tube ride up back of the epiglottis. I seized and extracted it by the tips of two fingers of the right hand. This was followed by the expulsion of false membrane and muco-pus. The child now breathed with freedom, and was perfectly comfortable. The following day the patient again became very cyanotic, and the tube was reintroduced. Almost immediately the same phenomena of occlusion of the tube occurred. The thread this time being still attached, the tube was rapidly withdrawn; the child expelled a quantity of false membrane, which had probably been loosened and dislodged by the introduction of the tube. It was not necessary to again intubate, and the child made a good recovery. In this case calomel vaporization was employed.

Case X.—L——, aged four, female. This was a very bad case, the dyspnœa had existed about twenty-four hours, with a great deal of false membrane in the pharynx and on tonsils, with considerable swelling of glands of the neck, as the child was extremely small for its age. A No. 2 tube was introduced, and with the expulsion of false membrane great relief was obtained, but the child died thirty-two hours afterward from extension downward. Calomel vaporization was employed in this case.

Case XI.—C——, aged five, female. Extreme dyspnœa. Disease had been present about one week; more or less croup during this period. Upon introduction of No. 3 to 4 tube the child coughed up a great deal of muco-pus, but no membrane, and became immediately relieved. Saw the child again thirteen hours afterward, sleeping quietly and breathing easily. Was summoned two hours later and found the patient moribund, dying at once. An autopsy was refused, the parents even forbidding me to remove the tube. Calomel vaporization was used in this case.

Case XII.—L——, aged three years and six months, female. Laryngeal symptoms had been present twenty-four hours. The child was suffering extremely when a No. 2 tube was introduced. Relief occurred at once, but death took place thirteen hours later from extension downward of the membrane. Calomel vaporization was employed in this case.

Case XIII. — H——, aged seven years and six months, female. This was a case of diphtheria following measles. A croupy cough had been present about twenty-four hours. After introduction of a No. 5 to 7 tube considerable muco-pus and a small amount of membrane were expelled. Child died three days afterward from extension downward. Calomel vaporization was employed in this case.

Case XIV.—S——, four years of age, female. Croup had persisted for twelve hours and the child was rapidly becoming cyanotic. Great relief was obtained upon introduction of No. 3 to 4 tube. The child was doing well, when it coughed up the tube sixteen hours afterward and died of suffocation before I could reach the house, though summoned at once.

Case XV. — G——, aged fifteen months, female. This was a very interesting case, but hopeless from the first on account of a capillary bronchitis complicating the croup, and the age of the patient. The patient had been sick at least a week when it was seen by me. A No. 2 tube was at once introduced, but did not give any appreciable relief, and the child died three hours later.

Case XVI.—B——, aged two years and six months, female. The child had been suffering from diphtheria with membranous deposits on tonsils and pharynx for six days. During the last two days croupy respiration was present. Great relief was obtained upon the introduction of tube No. 2. Forty hours afterward the patient died from extension of the membrane downward. Calomel sublimation was employed in this case faithfully, and for awhile with seeming benefit.

Case XVII.—G. G——, aged seven, male. This boy had been suffering from diphtheria ten days, the last five of which he had been croupy, which condition increased so rapidly on the tenth day that when I saw him he was suffering intensely from lack of air, and was old enough to appreciate the cause. Introduction of No. 5 to 7 tube was followed by instant relief. Fifteen hours afterward, during an attack of coughing, the father became frightened, thought the boy was choking, and pulled out the tube by means of the thread which was left attached. The patient breathed with ease for awhile, but twelve hours later it became necessary to reintroduce the tube. It remained in place about five minutes, when it was coughed out, and I introduced one of the next larger size; thereupon the child gagged and coughed, expelling the tube together with a complete membranous cast of the trachea and the bifurcation. After this the child's respirations were easy, and I left it without a tube. Three days later I was summoned hastily and found the child as before, cyanotic and greatly distressed for lack of air. I reintroduced the tube, and again it was expelled with another complete cast of the trachea. Then, as the patient seemed perfectly comfortable once more, we left him without reintroducing the tube. Calomel vaporization was begun at this time and the details carried out faithfully, and the child made a good recovery.

Case XVIII.—W——, aged five, male. This patient was seen on the fourth day of the disease. The membrane had already invaded the lung, and a No. 5 to 7 tube was introduced to see if it would make any difference in the respiration. There was but slight appreciable effect and the child died within an hour.

Case XIX.—D——, aged eighteen months, male. Child had been sick four or five days. There was membrane on the tonsils and pharynx, and the dyspnœa was extreme. Immediate relief was obtained upon introduction of a No. 1 tube, the child expelling a great deal of false membrane and muco-pus. Four hours afterward the child coughed out the tube, and it was not necessary to reintroduce it. The patient made a good recovery. In this case calomel sublimation was employed with considerable benefit.

Case No. XX.—B. W——, aged seven, male. This child had had influenza, followed by a slightly croupy cough lasting about two weeks, the last four days of which it grew steadily worse. The parents did not realize the gravity until the child's condition became critical, when I was called. Upon introduction of a No. 5 to 7 tube a small piece of membrane about one inch in length was expelled, together with considerable muco-pus. There was no membrane visible on the tonsils or in the pharynx; there was no elevation of temperature, and the child was apparently not sick except that there was the mechanical obstruction to respiration—which the tube removed. The patient wore the tube until the seventh day, when it was removed, encrusted with calcareous deposits—and the child was well.

In conclusion, of the twenty cases intubated six recovered—thirty per cent. Ten cases were treaterd with calomel sublimation in addition—of these three recov-

ered. The other treatment consisted in the administration of iron bichloride and stimulants, with the local application of peroxide of hydrogen.

56 West Fifty-sixth Street.

ADENOID GROWTHS OF THE NASO-PHARYNX.[1]

By T. C. EVANS, M.D.,

Lecturer on Ophthalmology, Otology, etc., Kentucky School of Medicine, Louisville, Ky.

In the animal economy we find a system or series of lymphoid or adenoid masses, situated in different locations along the alimentary canal and the respiratory tract, varying in number and location according to the habits and environments of the different species. These lymphoid masses appear to be modified or specialized lymphatic glands, or at least they are intimately connected with the lymphatic system. In man and other omnivorous mammals these masses of lymphoid tissue form a circle, or more properly speaking, two or more less complete circles, one surrounding the naso-pharyngeal portion of the respiratory tract, the other the oro-pharyngeal portion of the alimentary canal. These circles are often described as the lymphoid ring, and embrace the faucial tonsils, the pharyngeal tonsil, the glandular bodies at the base of the tongue, as well as many smaller masses. Besides the lymphoid ring, these masses are also found in the lower reaches of the alimentary canal, in the jejunum, and especially the ileum—here they are known as agminated glands, or "Peyer's patches." The exact function of these masses is still somewhat obscure, but it has been pretty clearly demonstrated that they possess a phagocytic action, the lymphocytes which make their way in and out these masses have the power of taking up the various forms of bacteria and destroying them. The process appears to be similar, or rather supplemental, to the general phagocytosis exhibited by the leucocytes of the general circulation. This phagocytic power is evidently intended to protect the animal against infection by ingested or inhaled bacteria. But in diseased conditions of these masses, instead of protecting against the introduction of bacteria, they become channels of invasion. The lymphocytes still possessing the power of migration, and of enveloping bacteria and carrying them from the surface, appear to have lost their bactericidal power; instead of doomed prisoners the bacteria become mutinous parasites, feeding and multiplying on the protoplasm of the cells, while they are being carried to a neighboring lymphatic gland.

In this paper I wish only to speak of the abnormal condition of those masses of lymphoid tissue situated in that part of the respiratory tract known and described as the naso-pharynx—the disease commonly known as adenoid growths of the naso-pharynx. Meyer, of Copenhagen, in 1868, was the first to fully describe this condition. Czrmak, in 1860, Volintini and Lowenberg, in 1865, all seem to have observed the phenomenon, but for some reason failed to appreciate its importance. So Meyer is considered, and justly so, the discoverer of lymphoid hypertrophies in the naso-pharynx.

The disease consists of an hypertrophy of the lymphoid tissue that encircles the naso-pharyngeal portion of the respiratory tract, blocking up the space and mechanically interfering with, or altogether inhibiting, nasal respiration. This hypertrophy usually involves, to a greater or less extent, the faucial tonsils and other contiguous lymphoid masses. Except that heredity seems to play some part in its production, and that it is essentially a disease of childhood, little can be said as to its etiology.

[1] Read at the Kentucky State Medical Society, Harrodsburg, Ky., June 16, 1895.

The diagnosis is easily made from the characteristic symptoms which have been so fully and frequently described. The open mouth, the elongated face, the expressionless countenance, the dead or nasal voice, the inability to articulate certain consonants, the viscid mucus, the disturbed sleep, with its sweats, snoring, and night-terrors, the chest deformity, deafness, and mental hebetude, all make a picture that can hardly be mistaken. But if these are not sufficient, positive evidence can be had by passing the index-finger into the naso-pharynx and making a thorough survey of its walls and contents. This procedure is easily accomplished; while causing considerable pain it cannot possibly do any harm. In older children some information can be obtained by the use of the rhinoscope. In addition to the impaired hearing, the deformities of nasal, buccal, and thoracic cavities, which are among the most distressing and persistent of the sequelæ, and have been recognized since the days of Meyer, I wish, also, to call your attention to another danger from diseased lymphoid tissue that has until quite recently been overlooked—that of a channel for tubercular infection. Though diseased lymphoid masses have long been recognized as fruitful source of infection in diphtheria and the exanthemata, attention was not called to the fact that they played an important rôle in tubercular infection until 1894, when Dr. Sims Woodhead delivered an address before the North London Medico-Chirurgical Society on "The Channels of Infection in Tuberculosis,"[1] in which he forcibly demonstrated the dangers from diseased lymphoid masses, especially the pharyngeal tonsils. In speaking of the part played by the "lymphoid ring" he said: "It is found when pigs are fed on tuberculous material held in solution, especially if the solution contains fatty or viscid material, that in a very large proportion of cases these animals become affected with tuberculosis of the gland associated with the tonsils." Further on he says: "So far as can be made out from a careful consideration of the results reported by observers who have collected statistics, and have performed feeding experiments, and from my own observation of a number of similar experiments, I am driven to the conclusion that this method of infection of the glands of the neck through the tonsils must be of comparatively frequent occurrence, especially in children living under unsanitary conditions, and subjected to various devitalizing influences."

After describing the process of invasion in the pig from the tonsil to the glands in the neck, and to the thorax by the mediastinal and post-sternal lymphatics, and by the intercostal lymphatics, until the glands at the root of the lungs become infected, he says: "Of course, in children it is not possible to demonstrate this line of invasion in the same way that one can in experimental animals, for the simple reason that in experimental animals the disease can be traced from the very earliest stages to the time at which marked external signs of tuberculous glands make their appearance; but sufficient can be made out by anyone who will classify the results of a large number of post-mortem examinations of children, when the conditions of the glands of the various parts of the body have been noted, to convince him that the process of invasion of the tonsil, or at any rate of the lymphoid tissue in this region, is of a comparatively frequent occurrence; much more frequent than even those who have examined a large number of cases of tubercle in children are at first inclined to suppose. The very cells, then, which in health have to do with the destruction of bacilli, and with protecting the organism against their invasion, are those which appear to be responsible for the conveyance of tubercle bacilli from the outer surface to the tissues beneath."

From the researches and experiments of Dr. Wood-

[1] Lancet, October 27, 1894.

head, it is evident that a considerable number of the cases of pulmonary tuberculosis, especially in early life, are secondary to tuberculosis of the bronchial glands at the root of the lungs, and that in many cases the channel of infection is through the pharyngeal or faucial tonsils. Besides the abnormal condition of the tissues themselves in hypertrophy of the pharyngeal tonsils, we have constantly present a surface of greater or less extent denuded of its epithelium, as is shown by the small quantities of blood which so often streaked the viscid secretion from the naso-pharynx.

I think it is reasonable to conclude that the enlarged cervical and bronchial glands which so constantly accompany lymphoid hypertrophies, are due to tubercular infection through this channel; that instead of being a part, a diathesis, or dyscrasia, which has generally been described as lymphatism or scrofula, they are most likely the result of tubercular infection through the diseased lymphoid masses, either of the pharyngeal ring or of the Peyer's patches.

To again quote from the article of Dr. Woodhead, he says: "I am sure that those of you who have made any considerable number of post-mortem examinations of the bodies of tuberculous patients, who have succumbed at various periods of life, will agree with me in this, that the affection of the lung often appears to (although the ultimate cause of death) be merely a secondary affection. I have seen case after case in children, and in animals fed on tuberculous material, the lung markedly affected, but in a large proportion of these cases it has been possible to trace the course of invasion back from a caseous or old calcareous mesenteric gland through the chain of retro-peritoneal glands, up through the diaphragm to the posterior mediastinal and bronchial glands, and so on to the lungs. I have not seen this in a few cases only, but in dozens of children, in a few adults, and in many animals. We also have an example of a secondary affection of the lungs following tubercle of the pharyngeal tonsillar structure, through the glands of the neck, then those in the thorax, and finally to the lung itself, in the examples that have already been given of infection of the pig by tuberculous milk."

In going into detail of dangers from tuberculous infection, somewhat to the exclusion of other symptoms and sequelæ of adenoid growths, I do not wish to be understood as underestimating their importance, but they have been so often given that a repetition is here unnecessary.

The treatment of adenoids of the naso-pharynx is either expectant or surgical. The probability of favorably affecting lymphoid hypertrophies by the use of drugs, either topically or constitutionally, is so remote as to scarcely entitle it to consideration. The expectant plan—the "outgrowing" process which the parents so confidently count on—has at least this advantage, that the hypertrophy usually diminishes with age, and sometimes entirely disappears with adolescence. The cavity of the naso-pharynx is proportionately larger, so that the respiratory obstruction, so far as the naso-pharynx is concerned, is diminished, or altogether disappears. On the other hand, the deformities due to years of mouth-breathing do not disappear with the "outgrowing" of the obstruction. The high-arched palate, the contracted nasal chambers, the deformed alæ, with their small, round nostrils, the listless facial expression, due in part to the deformity and in part to the impaired hearing, have by this time become so much a part of the physical make-up that neither time nor treatment can effectually efface them. The expectant plan is at best long, tedious, and uncertain, entailing years of suspense on the physician and parent, and subjecting the patient to dangers which, when once encountered, cannot be corrected.

In speaking of the removal or destruction of pharyngeal hypertrophies by surgical means, it will not be necessary to review the many operations that have been devised, and the almost endless list of instruments and appliances that have been invented for this purpose, most of which have for various reasons been abandoned. Most operators now confine themselves to one of the following methods, viz.: 1st, Removal by the post-nasal curette: the most efficient instrument is what is known as the improved Gottstein curette; with this it is possible to completely remove the hypertrophies from the dome and posterior wall of the pharynx without danger to the Eustachian tube or soft palate. It is the only instrument necessary for the operation, except occasionally, in intractable children, a mouth-gag will be of service. 2d, Removal by post-nasal cutting forceps: all the post-nasal are in fact modelled after the old post-nasal forceps of Lowenberg. I think the one in most common use at this time is what is known as Gradle's forceps, which consists of triangular fenestrated blades, the fenestræ being guarded by a shield to prevent the excised tissue from falling into the larynx. The only danger in the cutting forceps is to the soft palate, which can be held forward with the finger, or tied out of the way.

In this connection I wish to state that where, for any reason, it is necessary to hold the palate forward, it is best to at once pass a tape or soft catheter through the nose and tie the palate out of the way. None of the many palate retractors have in my hands been satisfactory. Instead of getting a view of the post-nasal space, I have usually gotten the contents of the stomach. Probably the chief question is whether or not general anæsthesia is required. The hemorrhage after the operation is quite profuse for a few minutes, making an annoying and troublesome complication in the use of anæsthetics. This danger can be lessened, but not entirely obviated, by the position of the patient during the operation, placing the head lower than the body so that the blood will gravitate away from the larynx. As a rule I operate without an anæsthetic. Patients who were old enough to talk intelligently have often told me that the curetting produces no more pain than the preliminary exploration with the index-finger. Cocaine seems to do little good in these cases, and is not well borne by children.

The dangers of the operation, other than those due to the administration of anæsthetics under adverse conditions, are almost nil. There is no shock, and the subsequent discomforts are rarely sufficient to confine the patient to bed. The galvano-cautery is only applicable in a small per cent. of the cases. It is indicated in the sessile or cushion-shaped growths. Such conditions are usually found during youth. In these sessile tumors the hypertrophy is of the connective tissue, rather than the stroma of the pharyngeal tonsil. Destruction by the cautery is generally regarded as the most conservative operation, but is the most difficult. The use of the galvano-cautery presupposes a tractable patient with a tolerant pharynx; an operator sufficiently skilled in the use of instruments to manipulate the rhinoscopic mirror with one hand, the electrode with the other, to locate and limit the point of cauterization by the image in the mirror. No one should be reckless enough to introduce a cautery electrode into the naso-pharynx without being able to watch and guard the process from start to finish. Electrodes are used both through the nose and behind the palate. The destruction of any considerable amount of tissue by the galvano-cautery is tedious, and will require many sittings.

Restoration of Joint Functions after Fracture.—Massage, soaking in hot water, frictions with liniments, electricity, passive motion, and attempts at voluntary movement continued for months, will often cause great improvement in the functional usefulness of joints supposed to be irretrievably damaged through fracture.—Roberts.

THE ABUSE OF MEDICAL CHARITIES.[1]

By FRANK VAN FLEET, M.D.,

NEW YORK.

OPHTHALMIC SURGEON TO RANDALL'S ISLAND SCHOOLS AND HOSPITALS; ASSISTANT SURGEON TO MANHATTAN EYE AND EAR HOSPITAL; INSTRUCTOR IN DISEASES OF THE EYE, AT THE NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL.

It is one of the crying outrages of the times that the free dispensaries in our city, and, I presume, the same may be said of all cities, treat, gratuitously, many patients who are abundantly able to pay for services rendered, and it is a melancholy fact that the number so treated is getting larger every year.

In the fourteen years that it has been my fortune to be connected with the different hospitals and free clinics devoted to the treatment of diseases of the eye in New York City, I have seen this evil grow until now it has reached such proportions that it seems to me that it may form a theme worthy our discussion in this medical body, with the end in view that, in a multitude of counsel we may devise some scheme whereby its evil tendencies may not only be more fully appreciated, but its future growth curtailed.

This abuse is an evil which we cannot continue to observe with indifference, for not only does it take away from the members of the medical profession what should be a legitimate source of income, and deprive the worthy poor, for whom these free institutions are intended, of the time and attention necessary for their proper treatment, but it also begets in the unworthy and undeserving recipients habits which tend to degrade them, the influences of which may extend far into the future, affecting not only themselves but generations yet unborn.

This growing tendency to get something for nothing is widespread, and has a deeper hold on the community at large than we are willing to admit; indeed, I believe it would be difficult to convince the public mind of its extent unless brought face to face with the facts. It may influence the skeptic, and cause him to stop and ponder, when I say that in the Manhattan Eye and Ear Hospital, where I have the honor to serve, out of 16,893 patients registered in all departments for the year ending September 30, 1894, 771 were refused treatment because of their ability to pay. This number, which is over 4.5 per cent. of all who applied for treatment, may or may not fairly represent an average that would apply to all institutions of its kind in our city; but, while we are as careful as we can be to sift out the unworthy, yet it is patent to all observers that many slip in who could, with justice, be excluded.

While not desiring to enter into invidious comparisons, I know that in our institution we treat a better class of patients than are found in some other clinics, and by better class I mean that we have more native-born Americans in the classes at the Manhattan—in the year above quoted sixty-one per cent. of our patients were native born. Yet I know that in clinics where the applicants are largely of foreign birth, a very large number are able to pay for medical services.

The subject I bring for discussion is not a trivial one, but one involving many intricate problems for its proper solution; I ask you, therefore, to bear with me patiently while I array before you some of the thoughts that have occurred to me while turning this matter over and over again in my mind.

In the first place, it is not an easy question to decide who is, and who is not, able to pay for medical advice, nor, deciding this, is it possible to formulate at once a system whereby we can correct the evil. It has occurred to me that in order to arrive at a proper solution of the subject, it will be well to consider the matter under the following headings, namely,

First. Who is, and who is not, able to pay for medical advice?

Second. What is the effect of the abuse of charities, medical and otherwise, on the public mind?

Third. Who or what is to blame for this abuse?

Fourth. What remedy, or remedies, shall we suggest to correct it?

The clinic cards of most institutions contain the statement that none are treated except those who are too poor to pay for medical advice. Services of one kind or another are paid for in various ways; the legal-tender, known as money, being the equivalent generally employed in civilized communities. But money is not the only medium of interchange; the medium may be anything the contracting parties mutually agree upon. The physician giving a part of his time to free dispensaries and hospitals does so with the distinct desire and understanding that in return for this consideration he shall receive experience, and, going into an institution where many people are treated, and where he receives the advice and aid of able superiors, he acquires a knowledge and prestige that places him in a position he could attain in no other way. His superiors, who grow old and gray in the service, and who from long observation become familiar with all the clinical features of every part of their specialties, find, perhaps, their only reward in having at their command material for teaching medical students, and both they and their assistants are looked upon, because of their hospital and dispensary connections, as authorities in their special lines.

The clinic patient gets treatment, and in return gives himself as material for observation and medical teaching; that he is well paid for this offering to science is attested by the fact that he is saved from blindness, disease, or death, and no liberties are taken with him, no operations or experiments are performed upon him, without his consent and desire. The obligation is not, therefore, all on one side, but is mutual.

Physicians, however, much as they would like to give their time to interesting hospital work, much as they would like to devote themselves to relieving the sufferings of afflicted humanity, for much of the work done is neither instructive nor pleasing, are forced, at least most of them, to do something more than this. The growing demands of civilization and individual advancement necessitate a style of living that requires something more than experience in scientific matters. It requires the possession of that other medium of interchange, money; an article many medical men, especially the younger, do not possess in abundance.

Now, if all people afflicted with sickness or defects applied to dispensaries for treatment, it would necessitate that the attending physicians have independent means. The management of these institutions have accordingly found it necessary to say who they will, or who they will not, treat, and have decreed that only those too poor to pay for medical attendance shall receive treatment without monetary consideration. The question we naturally ask is, What constitutes being too poor to pay for medical attendance? At most institutions applicants will be interrogated something after this manner: What is your name? Where were you born? Are you married or single? What is your business? What is your income? If married, How many children have you? From the answers given the deductions are drawn, which cannot be carefully done when, in the space of two or three hours, the entry clerk sees and records from sixty to a hundred patients. The final question, which may, or may not, be asked, is: Can you not afford to pay a physician? Almost invariably the answer comes, No! We have frequently found that this denial is a deliberate falsehood; yet in many instances people who are more able to pay than the physician is to give free treatment, truly feel that they are not. Let us consider a few instances.

Mrs. M——, who calls on her physician regularly,

[1] Read at the eleventh annual meeting of the Fifth District Branch of the New York State Medical Association, held in Brooklyn, N.Y., May 28, 1895.

and at the end of the year settles the bill at the rate of five or ten dollars per office visit, has in her employ a maid who has headache, or something of the kind, requiring medical advice. The maid receives a monthly wage of twenty dollars, and, of course, could not be expected to pay for two or three consultations all she could earn in a month. Mrs. M—— contributes yearly to certain dispensaries, and at once concludes that her servant had better go to one of them for treatment. There are many just such cases. School teachers, clerks, and a long list of workers of every kind, earning good salaries, justly feel that they cannot afford to pay big fees for medical advice. But these medical men, these specialists, do not invariably get, or even charge, big fees. Although they may have a fee which is, say ten dollars, they are willing to make reductions, and their books will show, at the end of the year, that if it were not for the patients who paid small fees, say one or two dollars, the mighty specialist would have had to curtail expenses.

There are many people who would rather pay a small fee than have free treatment, if they knew where to go; but there are also those who feel that after living as they like to live, dressing as they like to dress, and humoring all their desires and vanities, they are unable to pay for, let us say, having their eyes examined, especially as they want to get gold-rimmed spectacles. Now these people are not worthy objects of charity, and they should be refused treatment. A man who possesses and wears a diamond scarf-pin has no right to present himself for charity treatment. If he were to pay a physician for treating him and then help himself to somebody's diamond pin because he had no money left to pay for one, he would be designated a thief. But because he pays for the diamond and steals the medical advice he is no less a thief, although he may not violate the written law.

The woman who works for her living and dresses in silk and wears a sealskin cloak has no right to come to a free dispensary for treatment. The girl or boy, sixteen or seventeen years of age, attending school or college, richly dressed and wearing gold ornaments about their persons, have no right to come for free treatment, even though their parents may be hard-working mechanics. The attending physician justly feels that these people are enjoying profits that should accrue to the doctor and his family. Consider a case like this. Two well-dressed elderly men present themselves, having come from out of town. They are brothers, and one has cataracts that are ready for operation. The attending physician asks if he cannot afford to pay? Well, if it is absolutely necessary he may be able to pay something. He is told that this institution is for people who are too poor to pay even a small fee, and he is referred to the superintendent, who will furnish him with a list of the doctors connected with that dispensary, any of whom will treat him at reduced rates if necessary. The men depart, and shortly after the superintendent comes in to say that this man is a veteran, living on a pension, and has saved a little money, but cannot afford to pay. The gentleman who accompanies him is his brother and he is a wealthy man. Now consider the inconsistency of this. Why should a rich man bring his poorer brother to a physician and ask charity? Why does he not bestow the charity instead of asking it of a stranger? Again, a physician sends a patient with a note asking attention. The appearance of the patient indicates a comfortable existence, but, in answer to the usual question, denies ability to pay. Naturally this question follows, "Do you pay your family physician?" and the surprised answer comes, "Certainly." And so we could go on indefinitely. It seems to me that if we could eliminate from our clinics those who are able to pay for medical advice, a very large number would be rejected.

The person who is able to dress elegantly ought not to be treated free. We frequently say to people, "Really your dress does not seem in keeping with your request for charity;" but the pat answer comes that a person may have sufficient pride to dress well and yet not have much money. But such an answer should not be accepted. A person who is able to dress well has no business to ask charity; they have no right to rob Peter to pay Paul; if they want medical advice they should be compelled to pay for it with some of the money they would spend on their dress, or go without it. It may be true that they cannot afford both, but the physician should not be expected to make up the deficiency; he experiences enough of that deficiency often in his own family. Nor should the physician in general practice be allowed to send a patient to the dispensary for free advice when he gets a fee for his treatment. If the patient can only afford one fee, that should at least be divided with the consultant. A common example is this:

Mrs. B——, from Greenpoint, Long Island, presents herself with iritis, for which Dr. F——, after treating her for three weeks, sends her to the hospital with an introduction written on his card. Mrs. B—— is married, and has two grown children, who are self-supporting. Mrs. B—— herself keeps a fancy store. When asked if she cannot afford to pay an oculist she says she cannot. When asked if she paid Dr. F—— for his treatment, she says she did, and adds further, that he sent her to us, and he has been very kind to her. It certainly requires less effort and generosity when you can dispense charity at some one else's expense.

I believe that an adult, unmarried, and in robust general health, should not be allowed charity, unless too old to work. There must, of course, be exceptions, they may have some ailment that incapacitates them. To our eye-clinics, however, people come who have some ocular trouble which may not incapacitate them, but is simply an inconvenience. They are able-bodied mechanics, policemen, firemen, clerks, typewriters, bookkeepers, etc., male and female, unmarried, with no one depending on them for a living, and earning from twelve to twenty-five dollars weekly, and upward; they should not be allowed free treatment; they take up the time that should be devoted to worthier people; they rob the doctor of his just fee, but, worse than all, they degrade themselves, and sow in themselves the seeds of pauperism. They kill that feeling of independence and honor which should be, and is, innate to the character of the native-born American, without which we cannot be good citizens, and they lay the foundation of a system of beggary that shall curse and degrade, instead of blessing and elevating, their descendants.

The man or woman whose happiness, comfort, and continued ability to earn a living depends on their eyes, should be willing to share that advantage with the oculist—who puts them in a condition to do their work, no matter how small that consideration may be. If the man or woman have, depending on them for support, families, aged parents, and others, who would be deprived of necessaries if fees had to be paid to doctors, that man or woman has a right to ask that charity, which we, as physicians, are willing and glad to be able to bestow. But if we are asked to bestow charity that robust and able people may have luxuries for themselves and their families, luxuries we may not be able to obtain for ourselves, then we feel that we have a right to protest.

The effect of this abuse of medical charities is, as I have said above, degrading to the public mind, and its tendency is toward the increase of pauperism. The cardinal principle of American institutions is independence; a feeling which makes a man spurn with scorn an insinuation that he should be an object of charity. This is the feeling which actuated our forefathers, and made them feel that they had no right to anything they did not gain by toil; to accept charity was, to them, humiliating indeed. Increasing population, with its

necessary increase in competition, has gradually brought about a feeling that one is justified in getting all he can with as small an outlay as possible, a feeling increased and strengthened year by year by the influx of paupers from Europe, who, after years of frantic struggle with poverty at home, have been forced to come to our fair land in the hope of better things. They bring with them their begging, grasping methods, so necessary in their own lands to insure them a living at all, which, coming in contact with the free and independent American spirit, contaminates it. These people and their children are the ones who frequent our clinics. It would be impossible perhaps to eradicate this feeling from the immigrants themselves, that they are justified in getting all they can for nothing, but it would be well for us, as a people, if we could keep it from taking root in their children, and from them being disseminated to our own.

The indiscriminate distribution of charity, therefore, tends to destroy the sense of honor in the recipients, makes them unmindful of the rights of others, and begets pauperism.

Where shall we place the blame? It is difficult to say who is able to pay for medical services, but the effect of too much charity on succeeding generations is easily predicted. When, however, we come to the question as to why these charities are abused, we are confronted by a subject of such magnitude that one is at a loss to know just where to begin.

No one person, no one class of people, can be said to be wholly and exclusively to blame. The people, meaning the public, are to blame in a measure, the institutions and their attending physicians and surgeons partly, and outside medical men, with the laity, contribute their share. The fact, then, is that we are all, in a measure, responsible. Many people go to dispensaries for special treatment, simply because they do not know where else to go; they have no idea or notion of getting advice or treatment for nothing, but they have never heard of any particular specialist; they ask for one at the dispensary and expect to pay. Others go because they think they have a perfect right to do so. They think the city pays the doctors and supports the institutions, and that these places are for their benefit. They put ten cents or a penny in the poor-box and feel that they are charitable indeed; when refused treatment, because they are not worthy objects of charity, they become indignant and threaten all sorts of vengeance, such as complaining to the mayor or some other high official.

Others, seeing the reckless extravagance of some of the so-called charitable millionaires, feel that they may as well get some of the plums going. This is one of the unfortunate results of civilization and progress: the money, centring in the hands of a few individuals, leaves them a surplus which creates a corresponding deficiency somewhere else. With this surplus the multimillionaire builds hospitals and institutions which are often of doubtful benefit to mankind. That they are monuments to the liberality of their donors is true, but that they benefit the race I am not so sure. We have now in course of erection in our city a hospital, the construction of which will necessitate the needless outlay of thousands and thousands of dollars that might be put to better uses. There are a number of institutions in the city of New York devoted to charity, where, counting the running expenses together with the interest on the money invested in costly buildings makes the per capita cost of caring for inmates more than it would cost to board them in the highest-priced hotels in town. Surely this is a perversion of charity.

There are far too many hospitals and dispensaries, which continue to grow in number, not because there is really any need for more, but because one or more medical men want personal advertisement, or one or more millionaires want monuments to their generosity.

This is sad but true, and its effect on the public mind is not good. Doctors themselves are to blame for some of the abuse of medical charities. A case came to my notice a short time ago where a patient was sent to the clinic for eye trouble by a prominent physician in town, who was at the same time treating the patient in his office and being paid for his services. People frequently apply for treatment, or for a diagnosis, so that the family physician can treat them, and state that they are sent by their physicians for that purpose. Now, of course, this is a condition, despicable in the extreme.

A physician in general practice ought to, at least, be willing to divide with his colleague, and yet the medical men who abuse these charities are frequently the ones who complain most bitterly about the dispensaries interfering with their practice.

There is a feeling, or an idea, very prevalent, that specialists invariably charge and get enormous fees. This is, of course, an erroneous idea; it is the patients paying small fees who make up the bulk of the specialist's *clientèle*. When specialists were few in number they may have received larger fees, but, as every town and city has one or more experts in special lines, and as competition becomes greater, the size of fee necessarily diminishes. I think myself that the day of large fees is past.

There was a time when a few men had a monopoly of intelligence and ability, but in these days of post-graduate instruction it would be impossible to pick out one man who stands above his fellows; true, some are superior in many ways to others, but the best have so many peers that a line cannot be drawn. One man, or a few men, who charge large fees, cannot compete with many men, of equal ability, who charge smaller fees. It is said of one man in our city, who, when patients present themselves who cannot afford to pay a fee of ten dollars, informs them that they are charity patients and refers them to his clinic. This, if true, stamps him as unjust, not only to his fellow-practitioners, but to his patients as well. There are many physicians who would gladly treat these people for smaller sums, and people, as a rule, would rather pay a small fee than go to free clinics. One thing is certain; the men who have the largest practices, and are accordingly the best known, are the men who charge moderate fees. There is really no reason why a specialist should get a larger fee than the general practitioner; he renders no greater service. It is true he does what the family doctor often cannot do; but, on the other hand, the family doctor does what the specialist cannot do.

We find, then, three classes of people who frequent hospitals and free clinics.

The first class, composed of those who come, either because they do not know where else to go, or else have a mistaken idea that specialists charge such enormous fees that it would be impossible for them to afford private treatment. These people cease to be applicants for charity when given the proper information.

The second class, constituting, by the way, a goodly sized proportion of all who come, is composed of people in comfortable circumstances who are abundantly able to pay for medical advice, but who are referred to the dispensary by their family physicians, over whose motives we will draw the veil. The third class is composed of those who are downright frauds; they would pick your pocket, if they had a good chance, even while you are bestowing charity. They are the people who own tenements, and who, when they have ailments, put on tattered and worn clothing, and present themselves for free treatment. They are a bad element in society.

There is a fourth class, which may constitute twenty-five per cent. of all who attend; I doubt if it is much more. They are the deserving poor, driven to ask charity because of misfortunes of one kind or another,

and for whom we are willing, nay, eager to do all we can. It is the gratitude of this class that makes charity sweet, and the ingratitude of the others that makes it bitter. We come, then, to the consideration of the fourth heading of my discourse, namely, what remedy or remedies shall we suggest to correct this evil?

I would say that the first step should be an effort to raise the moral tone of society. Teach the people, first, that it is more blessed to give than to receive; second, that to accept charity under a misrepresentation of facts does not differ, morally, from taking that which is the property of some other person; and third, that these thieving actions tend not only to belittle themselves, but beget habits in succeeding generations which will dull that spirit of independence that should be our natural heritage, and, leaving them degraded will contribute to the development of a nation of paupers.

These strides toward that millennium when people seeing the right will do it, must, of necessity be slow, and in the interval let us insist that patrons of charitable institutions, and charitably disposed individuals generally, shall refer to free clinics for free treatment only people who are too poor to pay even the smallest fee; that physicians coming in contact with people who need the attention of specialists shall use the utmost discrimination, and not consider as fit subjects for charity patients who pay them fees, realizing that if patients can pay their family physicians they ought also to pay consulting physicians. Attendants, medical and otherwise, in free clinics should be taught that to treat people for nothing who are apparently able to pay for medical services is a perversion of charity and should, under no circumstance, be countenanced.

We have in our city a body, called the Charity Organization Society, that will investigate privately, through its agents, any person whose name is given and will report whether they are fit subjects for charity. This Society, which does a noble work, will report and investigate for anyone, whether a member or not; but as the yearly membership fee is small, it seems to me that it would be a good thing if every institution devoted to the distribution of charity would become a member, and thereby give financial as well as moral support to a good cause. Failing in this, I would suggest that every free dispensary and hospital employ an agent themselves, whose business it shall be to investigate doubtful cases. In this way a large proportion, if not all, unworthy applicants could be weeded out, to the end that not only would the noble cause of charity be elevated, but justice would be done to the worthy poor, and also to that large number of struggling physicians our medical colleges delight in turning out year after year.

Corneal Ulcer.—Dr. A. Llewellyn Hall, of Fair Haven, N. Y., writes: Cases of intractable corneal ulceration which have long resisted the usual methods of treatment quickly improve under the use of glycerite of tannin and carbolic acid prepared according to the following formula:

℞. Acidi carbolici..... grs. xv.
Acidi tannici..... grs. xxx.
Glycerini..... ℥j.
M.

Carefully cleanse the eye with warm sterilized water strongly impregnated with boric acid, introduce a few drops of weak cocaine solution to annul pain, and after a wait of five minutes freely touch the ulcer with the glycerite by means of a fine camel's-hair pencil. Repeat twice or thrice daily for the first few days and then gradually discontinue as healing progresses. In conjunction with this treatment it is well to maintain the usual instillation of atropin. Unpleasant reaction never occurs.

PRIMARY CARCINOMA OF THE HEAD OF THE PANCREAS, WITH HOUR-GLASS CONTRACTION OF THE STOMACH, SIMULATING DURING LIFE PYLORIC STENOSIS.[1]

By D. J. MILTON MILLER, M.D.,

PHILADELPHIA, PA.

The patient, a single woman, a domestic, aged fifty-three, first came under observation in the wards of the Episcopal Hospital, in February, 1894. At that time she gave a history of three months' illness, the principal symptoms of which were epigastric pain and occasional vomiting; the latter usually affording relief, and consisting of mucus and undigested food, and once of bright-red blood. The outlines of the stomach were apparently normal, and deep pressure in the epigastrium elicited pain, but there was no tumor. Günzburg's test revealed the presence of free HCl, but not in excessive amount, *i.e.*, the reaction, though well defined, was not intensely so. She had always been an excessive eater and a large drinker of tea, but never of alcohol. There was no family history of note. Under rest and a diet of peptonized milk she rapidly improved, and within three months was discharged, a diagnosis of chronic catarrhal gastritis having been made.

On November 3, 1894, she was readmitted into the Episcopal Hospital. It was then noted that she had lost considerable flesh and was quite anæmic. She reported marked increase in, and almost constant, pain and frequent vomiting—on several occasions of pure blood, or the so-called "coffee grounds" material. There was no tumor discernible. The outlines of the stomach, as defined by auscultatory percussion, appeared to be normal, and remained so throughout the whole history of the case. Examination of the gastric contents after Ewald's test-meal gave a faint reaction with Günzburg's solution. The contents had a strongly acid odor, reacting promptly to blue litmus paper. By the latter part of December a small, immovable, ill-defined, and very tender tumor could be felt in the epigastrium, two inches below the ensiform cartilage. Shortly after admission peptonized milk in small quantities was ordered, and daily lavage was practised. To effect this, a large amount of water was used, and it was noticed that, although the washings were done in the morning, they contained quantities of food given the day before. This occurred even when no food or milk had been taken for twelve or fourteen hours. About the 20th of January, 1895, a light jaundice was noted. This grew more intense, and was accompanied by an increase in the hepatic dimensions, and by the development of an oval, elastic, and semi-fluctuating tumor at the tip of the ninth right rib; this was thought to be the gall-bladder.

Several examinations during the course of the disease failed to give constant evidence of the presence of free HCl. This was probably due, as the sequel will show, to the failure to thoroughly wash out the stomach on the night previous to the administration of the test-breakfast—a precaution that should never be omitted, if we desire correct results in chemical examination of the gastric contents. The salol-test for the motor function of the stomach was also employed, but with unsatisfactory results.

During the latter third of the patient's life the stools were frequently, but unsuccessfully, examined for evidences of fat. A microscopic examination, however, was not made. The urine, though tested on several occasions, contained neither sugar nor albumin.

By February 25th the epigastric tumor was more defined, and still very painful and immovable. Otherwise the patient's condition continued about the same. Sometimes vomiting daily for a period, and then a week or ten days elapsing with entire freedom from this

[1] Read before the Philadelphia Pathological Society, May 8, 1895.

symptom. Pure blood was never vomited while under observation, though the so-called "coffee grounds" matter was ejected on several occasions. At this time Dr. D. D. Stewart kindly saw the case, and consented to undertake an examination of the gastric contents with the view of determining the absence or presence of lactic acid. In order to eliminate all sources of error, the organ, at Dr. Stewart's suggestion, was thoroughly cleansed prior to the administration of Boas's flour soup. In doing this forty-eight quarts of water were used. In the withdrawn contents, Dr. Stewart found a total acidity of 88 ; .05 of free HCl ; sharp reaction with Günzburg's test ; and no lactic acid. In the light of this examination a probable diagnosis of cicatricial stenosis from old ulcers was made.

From the 25th to the 28th of February the patient was fed exclusively on meat broths, milk being entirely withheld ; on the latter date the stomach was again thoroughly washed out with a solution of soda (sod. bicarb., ℥ ss. ; water, Oij.). It took but eight quarts on this occasion to cleanse the organ. The flour soup was then introduced through, and before removing, the tube, allowed to remain in the stomach over night, and withdrawn the next morning by aspiration.[1] Dr. Stewart's examination of this was as follows : Contents received, 360 c.c. ; strong odor of salol (given six days previously) ; total acidity, 70 ; sharp Günzburg ; free HCl, 0.175 ; combined and free HCl (Leo's method), 0.02225 ; no lactic acid ; egg disk completely dissolved in three and a half hours.

On the 7th of March tympanites developed, and there were signs of commencing cardiac failure. Various measures were employed to relieve the abdominal distention, but with indifferent success. The patient gradually grew weaker and died March 13th. It should be added that no enlargement of the supraclavicular and inguinal glands was at any time present, and that the temperature ranged between 98° and 99.5° F., occasionally reaching 100° F.

Autopsy.—Body emaciated. Skin and mucous membranes deeply tinged with bile. Pleuræ adherent at various points. Lungs pale, except at posterior bases, where there is hypostatic congestion. Slight amount of fluid in pericardium. Heart small, muscle pale, valves normal. Stomach and intestines strongly distended with gas. Stomach occupies an almost vertical position, the whole of the organ lying to the left of the median line, the lowest extremity on a level with the umbilicus. The pylorus is at a point midway between the ensiform cartilage and the umbilicus. On a line with the pylorus, and involving the whole circumference of the stomach, is a constricting band, which divides the organ into two parts : the lower, consisting of about one-third of the stomach, is thus separated from the body of the viscus by a rather narrow opening. The diameter of the stomach is lessened about one-half at this point. The portion above the constriction is of about normal capacity, while that below seems dilated. (Owing to rupture of the walls before the removal of the stomach, the exact capacity could not be tested, but the constricted portion evidently held about sixteen fluid ounces, the rest of the organ about two pints.) The mucous membrane is softened (post mortem) and in a state of catarrhal gastritis ; but there is no evidence of cicatrization at the site of the constriction or elsewhere. The pyloric orifice is little, if at all, narrowed, as it admits the forefinger with ease. The head of the pancreas is the seat of a hard tumor, about the size of a hen's egg, which completely surrounds and occludes the pancreatic and common bile-ducts. As a result the body of the pancreas is enlarged and softened, its duct dilated and filled with retained secretion. Behind the obstructed portion, the common duct is dilated and filled with dark bile. The cystic and hepatic ducts are also dilated, while the gall-bladder is enlarged and distended with fluid bile. The liver is enlarged, bile-tinged, the ramification of the hepatic duct filled with dark-greenish fluid. There are no secondary growths. The condition of the other organs is unnoteworthy. Dr. McFarland, pathologist to the Episcopal Hospital, examined the pancreatic growth, and reported it to be carcinoma.

This case presents many points of interest. In the first place, it emphasizes the value and the necessity of the modern methods of research in the diagnosis of obscure affections of the stomach and pyloric zone. The clinical history above narrated certainly warranted the diagnosis of malignant stenosis of the pylorus, with secondary involvement of the liver, or, at least, of the glands in the hepatic fissure ; but the constant presence of free HCl (although by our imperfect methods this was often absent), and above all the absence of lactic acid, enabled us to exclude gastric cancer, and led us to attribute the symptoms to a cicatricial stenosis of the pylorus, hypertrophic in character, occluding the common duct, with possibly a concomitant carcinoma of the pancreatic head. The autopsy showed the latter surmise to be true. There was no stenosis, but a remarkable constriction of the whole circumference of the stomach, forming the diverticulum above mentioned, and accounting for the signs of dilatation during life, and the difficulty in washing out the organ, the food collecting in the constricted portion. It explained, also, why auscultatory percussion failed to reveal the true dimensions of the organ, the stomach note being lost as soon as the space separating the two portions came under the percussing finger. This contraction was evidently congenital, as there was not the slightest evidence at the autopsy of cicatrices at the site of the constriction. Contractions of the stomach seem to be rather rare anomalies, as the few works we have referred to make little or no mention of them. This seems to be an instance of exaggeration of the antrum pylori (the lower quarter lying in front of the pylorus), which Ewald [1] mentions as causing the stomach, without the action of cicatricial contraction, to assume the shape of an hour-glass. Another interesting feature is the confirmatory evidence which our case gives of Boas's and D. D. Stewart's [2] work on the value of the presence of lactic acid as a sign of carcinoma of the stomach. The gastric catarrh was evidently sympathetic in character, and the weakening and dilatation of the constricted portion sequential to this. Until the onset of the pancreatic disease the diverticulum must have been able to empty itself, as there were no symptoms before that time. With the appearance of the carcinoma, however, and the consequent gastritis, the motor power of the stomach was impaired, and signs of dilatation became evident.

As to the pancreas, a comparatively uncommon condition is presented in the limitation of the malignant growth to the gland alone. In only 12 out of 127 cases of pancreatic cancer collected by Segre,[3] was the disease confined to that organ. It is quite possible that the pancreatic disease might have been detected with more certainty during life, had closer attention been paid to the presence of fat in the stools and glycosuria ; but owing to the prominence and interesting features of the gastric symptoms, the stools were not examined microscopically, and the urine was tested but a few times.

[1] These manipulations were carried on under Dr. Stewart's directions.

Buboes.—Treatment for this consists in, first, thorough antiseptic cleansing of operative region, followed by puncture and complete evacuation of the pus. Ten per cent. iodoform vaseline mixture, liquefied by heat, is then injected and a bichloride dressing applied.—FONTAN.

GLIOMA—OPERATION, CAUTERY, RECOVERY.[1]

By WILLIAM CLARENCE BOTELER, M.D.,

PROFESSOR OF OPHTHALMOLOGY, OTOLOGY, AND RHINOLOGY, COLLEGE OF PHYSICIANS AND SURGEONS, KANSAS CITY, KANS.

This disease, variously styled gliosarcoma, fungous hæmatodes, small-celled sarcoma of the retina, by different pathologists, was first described by Mr. Wardrop during the early part of the present century, and although the light of science has since then permeated every tissue-element of the body, from 1836 to the present time authors have not differed greatly as to the prognosis and treatment of this affection. In 1846 Dr. Little said: "This disease is a constitutional and fatal one, from which even the knife of the surgeon affords scarcely a probability of escape, the malady having, with few exceptions, reappeared after extirpation, though the operation was performed in the incipient stage and under circumstances the best calculated to insure success." Etiologically and histologically the earlier authors of America did not attempt to describe it; but more latterly the affection has been by some considered as arising from the "optic nerve," "the retina and optic nerve," or "the retina" alone, the latter being that now generally accepted. Dr. J. R. Wolfe, of Glasgow, Scotland, in his text-book of 1882, seems to localize the disease as first commencing in the optic nerve. Schmidt Rimpler, of Marburg, Prussia, revised by Roosa in his text-book of 1889, does not offer any original investigations or opinions as to the genesis or histology of the affection, but after quoting Virchow as the first to describe it as glioma of the retina says: "It unquestionably originates in the internal granular layer of the latter." Professor Soelberg Wells, in the last edition of his great work, revised by Dr. Charles Steadman Bull, of New York, ascribed its origin to the interstitial connective tissue of the retina, and Dr. Ernest Fuchs, of Vienna, brooking no reasonable doubts on this question, classifies the condition as glioma of the retina, and depending also on the researches of Virchow, says "it develops mainly from the inner granular layer of the latter." But as it is a connective-tissue growth, Iwanoff logically concludes "that it may originate from the connective-tissue elements of all or any of the layers of the retina." The tumor is an aggregation of roundish, granular, nucleated cells, with little intercellular substance.

Histologically, authors have agreed that it is identical with the small round-celled sarcoma, and that microscopically there was no difference between the two. But very lately Dr. Ernest Fuchs claims "that a microscopic difference does exist in that the cell of the glioma is never pigmented." Clinically all authors and ophthalmologists generally agree upon the usual rapid development of the growth, its tendency to invade adjacent structures, to the "metastatic development of tumors in distant organs, on its usually fatal termination despite operative measures and all that can be done." In a busy ophthalmological practice of seventeen years, I have had personally but four of these cases. All of them were little boys, three or four years of age; clinically they were all mainly similar; exenteration of the orbit was done in each case; three died and one recovered; two of the cases had reached the fourth stage, and two, including the one recovery I have now to report, were in the third.

Few cases of the disease have been reported where recovery followed, although Professor Panizza, in 1846, referred to a case in the person of "a man" whom, he averred, he had known to get well. Dr. Fuchs says "while the disease is still confined to the eyeball we may hope for permanent recovery, but when it has perforated the eyeball, rapid recurrences both in loco and in the neighboring lymphatic glands seldom fail to occur." Professor Soelberg Wells asserts, "the prognosis is always extremely grave and we have no guarantee at any time that the nerve is not already implicated although the tumor may be still very small." Professor Schmidt Rimpler agrees mainly with Wells, but alleges that "recoveries may be had from early operation."

The disease seems to be unquestionably one of childhood, despite some questionable cases reported in adults, and from its early manifestations in many cases it is not unreasonable to suppose that it may have its origin in early fœtal life and in traumatisms inflicted in the progress of labor. The symptoms as a rule are as follows: In early appearance the eyeball, as a whole, is quite healthy and normal; there is neither pain, congestion, nor inflammation; the pupil is slightly dilated, and on closer inspection a yellow-whitish reflection is seen from its centre, due to the growth of the disease and the detachment of the retina which it pushes forward. As the growth increases, the tension of the eyeball is vastly augmented, its size is exaggerated, the lens becomes opaque, and the lens and iris are pushed forward against the inner surface of the distended and overgrown cornea. At this stage for the first time the patient experiences pain. When the fungous-appearing tumor has filled the cavity of the eyeball, and the latter is more hideous and larger than the eye of an ox, perforation generally takes place. At this stage the tumor sprouts forth from its environments in red cauliflower form, and being unconfined, its growth is exceedingly rapid. A sanious liquid exudes from its surface, the eyelids are greatly swollen, the tumor bleeds on the least touch, and by way of metastasis the disease invades the neighboring lymphatic glands, the internal organs, generally the liver, and patients die in from a few months to several years, either by exhaustion or an extension of the dreadful disease to the brain. Notwithstanding the clinical history just given of this disease and the universally unfavorable prognoses quoted, I have one recovery to report from my only four cases.

B. T——, aged three and one-half years, was brought to me from Centralia, Kan., in January, 1893, for investigation as to the condition of one of his eyes, which had been noticed from birth to possess "some peculiarity." He was of the blond type, reasonably well nourished, but his general development showed a frail constitution. The mother, possessed of all the keen intuitions of intelligent womanhood, complained "that from inattention by a physician at birth or during delivery the child's eye had sustained injury, and during the first hour of life they noticed there was something wrong with it." There was no knowledge of scrofula or cancer in the families of either the father or mother, nor of any injury that could have been inflicted at play at any time. These parents had another child, a boy, then six years old, with good eyes and average health and strength.

This peculiarity had been noticed many times from birth by the mother, who frequently wondered at the shining of the ball like a cat's eye in a darkened room. When the case came to me for examination there was no inflammatory symptoms and the history given by the parents showed there had been none; but toward the last the part had become irritable and the child complained of pain. The first and second stages of the disease having passed when the case was presented, the third stage being in its meridian of advancement, the diagnosis was easy. The pronounced enlargement of the eyeball to three times its normal dimensions, being the size of a common egg; the presence of the rectinal excrescence, and the yellow characteristic reflex in the distended pupil of the hypertrophied eye; the high tension; the exaggerated size, projecting from the orbit, and disturbed relations of all the parts of the eyeball; the presence of commencing ulceration at the sclero-corneal junction where the overstretched

[1] Read before the Kansas City Medico Chirurgical Society of the College of Physicians and Surgeons, January 15, 1895.

tunics had begun retrograde metamorphosis, showed a most typical case of glioma retina of the third stage.

We could find no symptom that indicated the extension of the disease to adjacent parts (the fourth stage), and from the seeming freedom of the brain, liver, and lymphatics from metastatic implication, we gave the parents a ray of hope that a thorough, complete removal of the contents of the orbit might save the patient's life; the slow development of the growth, three and one-half years, lending courage to our assertions. The usual fatal termination of glioma, the steps of the operation, the necessity of chloroform, the liability to regrowth of the mass, having been explained, the parents readily consented to complete amputation of the contents of the orbit. This was done, as stated above, about the middle of January, 1893. There was no particular effort made at simple enucleation, but after dissecting the conjunctiva, transversely separating and holding it aside for future use, the entire contents of the orbit were exenterated or dissected away, the optic nerve divided by pointed scissors at the apex of the orbital cone; then the same thoroughly cauterized by an applicator carried to white heat with a spirit-lamp. The orbit was packed with absorbent cotton saturated with hydrg. bichl., 1 to 2,000 grains. It was dressed antiseptically in the same manner for two weeks, when the child and its parents returned to their home. At the present writing, January 15, 1895, almost two years from the time of the removal of the mass, the mother writes me as follows:

"Dear Doctor: After your operation in January, 1893, we dressed our son's eye with a syringe every other day until the following May; every day during the summer until October. Since that time we have dressed it only with the idea of cleanliness, and have not had any trouble with it. The remaining eye seems strong, and he is enjoying very good health."

Since Professors Fuchs, Wells, Wolfe, Virchow, Graefe, etc., concede "the children generally die either from exhaustion, or extension of the disease to vital organs, especially the brain," it seems reasonable that, from the absolute restoration to health of the little child above, we have here a result that would have been unusual in the experience of these great authorities, and one that deserves to be classed with the very few recoveries from this disease sparsely referred to by the great masters of ophthalmology of the world.

Progress of Medical Science.

Appendicitis.—Dr. Murphy believes that there has been no controversy in the history of medical science in which the struggle has been so intense between the surgeon and the physician as that concerning appendicitis. Differences of opinion in regard to the clinical course and propriety of operative and non-operative methods have been almost entirely due to erroneous notions of the pathological conditions. It is now settled that all, except two per cent., of the inflammatory lesions about the caput coli are due to primary lesions of the appendix. Observation shows that in the acute stage the pus is found outside the appendix in ninety-four per cent. of the cases, and that this does not necessarily indicate a perforation of that organ. Invasion of the peritoneum and formation of a peri-appendicular abscess may occur with an internal ulceration of the appendix without perforation. Finally, the points still in dispute are the pathological changes produced by perforation into the peritoneal cavity; the likelihood of that perforation, and also perforation of the circumscribed abscess about it into the peritoneal cavity; the immediate and remote symptomatic and physical manifestations of the latter, and the ultimate result of such rupture. The pathological changes produced depend on the character of the material admitted into the peritoneal cavity, whether it is pus or bacilli in which the staphylococcus predominates, whether the bacillus coli communis exists in its virulent or inert condition, and whether the parts, in which any or all of these may have existed, have become innocuous. It also depends on the quantity of material admitted at one time into the peritoneal cavity, on the condition of the peritoneum at the time of formation of the pus. Only two per cent. of the cases of appendicitis are found to contain foreign bodies, and fecal concretions are found in thirty-eight per cent. The other cases are: 1. Simple pus infection, producing the catarrhal variety. 2. Excessive infection by the bacillus coli communis, or by pyogenic microbes, producing gangrene of a greater or lesser portion of the appendix. 3. Pressure atrophy, with infection of the appendix (*a*) by fecal concrement, and (*b*) by foreign bodies. 4. Retention accumulations (*a*) from cicatricial contractions, stenosis, and obliteration, and (*b*) from occlusion by enteroliths or foreign bodies. Perforation was found in seventy per cent. of the reports of autopsy collected, and in his own cases it occurred in eighty-seven per cent. We have no sign, symptom, or combination of signs or symptoms, that indicates with any degree of certainty suppurative peritonitis in the early stage. The rule first, last, and always, should be, operate in every case of appendicitis, promising or unpromising, at the earliest possible moment.—*Philadelphia Medical News.*

Heart Disease and Menstruation.—Dr. Gow recently read a paper before the Obstetrical Society of London, with a record of 50 cases of this kind. In 28 the flow was unaltered; in 17 the flow was absent or scantier than before; in 5 the flow was either more profuse or recurred more frequently than before; in no case was there good evidence that heart disease gave rise to severe menorrhagia. It would seem that either amenorrhœa or scanty menstruation was a far more common accompaniment of heart disease than menorrhagia. A further analysis of these cases seemed to point to the fact that heart disease led to relative sterility, and also that it greatly increased the tendency to premature expulsion of the ovum. In conclusion, it was pointed out that a large number of women suffering from valvular disease of the heart pass safely through the period of pregnancy and labor. The cases were further analyzed as follows: 1. Mitral stenosis (22 cases). In 9 cases menstruation was regular and the amount lost unaltered, in 5 cases menstruation was regular but more scanty, in 4 cases there was amenorrhœa, and in 4 cases menstruation was either more frequent or more profuse. 2. Mitral incompetence (15 cases). In 10 cases menstruation was unaltered, in 4 cases menstruation was more scanty, and in 1 case there was amenorrhœa. 3. Mitral stenosis and incompetence (7 cases). In 4 cases menstruation was unaltered, in 1 case menstruation was more scanty, in 1 case there was amenorrhœa, and in 1 case there was slightly increased menstrual loss. 4. Aortic incompetence and obstruction (2 cases). In both cases menstruation was unaltered. 5. Aortic and mitral incompetence (3 cases). In all cases menstruation was unaltered. 6. Aortic incompetence and obstruction and mitral incompetence (1 case). Menstrual loss was more scanty than before.—*The Lancet.*

Inversion of the Vermiform Appendix.—1. Inversion of the stump of the appendix should be substituted for ligation in all cases of acute appendicitis in which it can be applied. 2. In chronic appendicitis either the entire appendix or its stump should be inverted, preference being given to inversion of the uncut appendix whenever practicable. 3. In all cœliotomies undertaken for the relief of conditions other than appendicitis, the normal appendix, if readily and safely accessible, should be inverted entire.—Edebohls.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 43, 45, & 47 East Tenth Street.

New York, August 31, 1895.

THE PHYSIOLOGICAL ACTION OF THE EXTRACT OF THE SUPRA-RENAL CAPSULE.

SEVERAL papers on this subject have been published in the *Journal of Physiology*. Dr. G. Oliver and Professor Schäfer report the results of their experiments with the extracts injected into the cow, sheep, and dog. They found that when the substance was introduced into the vein of an animal, it produced a rapid contraction of the arteries, a rise in blood-pressure, and a stimulation of the vagus nerve which was very pronounced Respiration was but slightly affected. They found that the extract acted about the same, whether taken from the calf, sheep, dog, cat, guinea-pig, or man. Further investigations along the same lines show that the introduction of these extracts into the system, while producing very striking effects, never led to a fatal result. It was also found that the active part of the capsule was the medulla, while solutions of the cortex seemed to have very little effect. They found also that the extract made from the glands taken from cases of Addison's disease had no activity. The authors were led to the conclusion that the extract was not influenced by hepatic digestion and could be taken by the stomach. On the whole, the results of their experiments were to show that the active substance in this gland has an extremely powerful influence upon the nerves controlling the heart and circulatory apparatus, and they further concluded that the gland is not destructive in its function, but rather secretory, that is to say, that it does not select effete matter from the blood, but pours some substance into the blood which is of great importance to the economy.

Dr. Moore, of the University College, has contributed an elaborate paper on the chemical nature of the active substance occurring in the supra-renal gland. He finds that its active principle is soluble in water and in dilute alcohol ; that it is not affected by acids, nor injured by boiling for some minutes, but is destroyed by alkalies and oxydizing agents ; it does not reduce Fehling's solution, and it is not volatile ; it dialyzes freely through parchment paper, and the substance so obtained is free from proteids.

M. V. Nabarro also contributes an article on the chemical properties of the supra-renal extract, but the descriptions are too technical to be of interest to the general reader.

It seems to be pretty well established that the gland does contain a powerfully active poison, which has certain definite chemical properties, and which is, perhaps, one of the nucleo-albumins.

COUNTER PRESCRIBING.

SOME criticism has been excited by the action of the County Medical Society in bringing suit against a druggist of this city for violation of the medical practice law. The *Financial Review* states that the druggist in question was a man in good standing and experienced in his profession. He was arrested through the instigation of the County Medical Society and brought before the Tombs Police Court. The presiding magistrate expressed the opinion that the druggist had the right to do what he had done, and added that if he had known the circumstances in the first place, he would not have issued the warrant for the arrest. The *Review* states that the charge against him was absurd, and was "evidently the result of that professional bitterness which so many physicians feel toward druggists in consequence of what they designate as 'counter prescribing.'" The fact, adds the *Review*, that the child for whom the medicine was prescribed by the druggist, died, proved nothing, since patients of physicians sometimes die also.

We are not, we confess, familiar with all the facts on each side of this question, but we do know that the general attitude of the County Medical Society toward "counter prescribing" has been a very conservative one. When one compares the enormous amount of counter prescribing by druggists of this city with the very few prosecutions, it would be apparent to everyone that there is no "professional bitterness" of any moment, in this city, at least. The habit of druggists of prescribing simple remedies for simple complaints is well enough, and is, no doubt, of service to the poor. It is only the systematic abuse of it which is dangerous to the public health and individual lives, and it is upon this ground, as well as upon the ground that it interferes with the work of the physician, that the medical profession protests against it.

TRAUMATIC PSYCHOSIS IN A HORSE.

DR. CHARLES FÉRÉ gives an account of a horse with a curious nervous disturbance, which seems to resemble in many respects a form of confusional or stuporous insanity in man. The condition, he says, is one not unknown to veterinarians and is described by them as "immobilité."

The animal in question was six years old, vigorous, and without any morbid heredity, and perforce of regular and temperate habits, being in active service on a truck. One day there was an accident and the horse and cart were thrown down a bank, a distance of about eighteen feet. The horse was apparently in no way injured and for several days continued his usual work. Then it was noticed that he began to get dull and apathetic, his eyes would become fixed, he paid no attention to his surroundings, and did not recognize or notice those who were accustomed to attend him, and

whom he had previously shown that he remembered. This apathy increased, and he would sometimes place his head on the edge of the manger and so remain for hours without moving or noticing his food. When this was pushed into his mouth he would often let it fall out. If one leg were taken and crossed in front of the the other, he would let it stay there. It was only by the greatest exertion that he could be hitched to his cart and forced to move. While going along the road the horse sometimes suddenly fell down, to the great disconcertment of his driver. At other times, after walking slowly and apathetically for a time, he would suddenly break into a furious and dangerous burst of speed. After such outbursts he would become more "immobile" than ever. His condition differed on different days, but on the whole he grew more lethargic, emaciated, and cataleptic. He never became maniacal, and did not kick or bite.

The outcome is not distinctly stated by Dr. Féré, but at the time of report the owner had decided to send him to a butcher, and perhaps the finale was sausages and steaks. We regret that no autopsy was made, but the reporter assures us that in other and similar cases there had sometimes been found a dropsical condition of the brain, while at other times no lesion couldbe discovered.

Bouley refers to this condition of the horse under the name of *immobilité*, and Chaslin describes it in man as "confusion mentale primitive."

Perhaps some of our readers have had personal experiences with "immobility" in the horse, though the condition known as *Langsamkeit* or *nature tardive* is more common in the domesticated specimens of this country.

NEW EDITIONS OF MEDICAL MEN.

Dr. William H. Thomson has recently suggested that it is the duty of the physician to get out a new edition of himself at certain stated periods. This is another way of putting the fact which the late Sir Andrew Clark used to call attention to: That a man was never old as long as he had not lost his receptivity, his capacity to learn and to adjust himself to the progress of the world. The figure of speech adopted by Dr. Thomson, however, is a very suggestive one, and we have no doubt that its current use would have a great deal of practical value. Dr. Thomson suggests that one reason why the country practitioner falls behind is that he gets into certain ruts and is too idle or too busy to get himself out of them. It is the country practitioner, he thinks, that especially needs a new edition of himself. Not that he is inherently less ambitious or more indolent than his city brother, but because the publishing offices and means of issuing "new editions" are mainly in the large centres. The establishment of graduate schools for the instruction of medical men has enabled practitioners to use the facilities that modern science brings out freshly every year, and we fancy in the course of time it will be the city doctor who will be behindhand in editing himself, for he is generally too thoroughly confident of his medical equipment to think it worth while to take a course of instruction from his fellowman.

News of the Week.

The Society of Medical Phonographers held its first annual meeting in London on July 30th. Addresses were made by the President and founder, Dr. W. R. Gowers, Sir Henry Howorth, Sir William Broadbent, and Mr. Thomson, and letters were read from General Sir Charles Wilson, the Bishop of Hereford, and Dr. Gladstone. The President said that Dr. Langdon, of Cincinnati, though forty-five years of age, had, in a fortnight, obtained the power of writing a shorthand letter which he (Dr. Gowers) was able to read as swiftly as he could speak, but he did not say how long it took Dr. Langdon to write the letter.

Cronica de Ciencias Medicas de Filipinas is the title of a new journal published in Manila under the editorial direction of Dr. A. Alfonso Maseras.

Anthrax in New York State.—The State Board of Health has found that anthrax prevails among cattle in many parts of New York. The Board has been conducting investigations looking to the discovery and extermination of bovine tuberculosis, and this led to the discovery of the rather wide prevalence of anthrax. The Board is empowered to deal summarily only with tuberculosis, and must look to the Legislature for power to destroy animals infected with anthrax.

The Intercolonial Medical Congress of Australasia will hold its opening session on February 3d next, instead of February 17th, as at first announced.

A Representative of the University Regents in New York City.—The Regents of the University of the State of New York, in response to urgent requests, have decided to open an office in this city for the accommodation of the immense amount of business which comes from here. The office will be at 10 East Forty-second Street, and will be open after September 10, 1895, during the school week, from 9 A.M. to 4 P.M., and 7 to 9 P.M. Business hours will be from 9 A.M. to 12 M., but the deputy, Mr. Aza O. Gallup, will see callers at other hours if they cannot come between 9 and 12. The representative of the Regents will have all publications, blanks, and necessary records for the accommodation of law, medical, dental, and veterinary students, and for all the professional, academic, and higher examinations conducted by the University.

The Weber-Parkes Prize.—This prize was founded by Dr. Hermann Weber in memory of the late Dr. E. A. Parkes. It is of the value of about $750, and will be awarded triennially to the author of the best essay upon some branch of the subject of tuberculosis, especially with reference to pulmonary consumption in man. The first award will be made in 1897, and the adjudicators have selected as the subject for the essay "The Means, Prophylactic or Curative, deemed by the Author to have Value in the Control of Tuberculosis, especial Regard being had to their Application to Human Tuberculosis." This subject was selected by Dr. J. E. Pollock, Dr. Thorne Thorne, and Professor W. S. Greenfield, who were nominated by the President of the Royal College of Physicians of London, and the

merits of the competing essays will be determined by the same men. The essay must be based on original work and observations (experimental or other) of the author, and must include a detailed exposition of the methods employed and their mode of application. The competition is open to members of the medical profession in all countries. The essays must be typewritten and in English; or if written in a foreign language must be accompanied by a translation into English. The essays must be delivered to the Registrar of the Royal College of Physicians on or before July 1, 1897. In addition to the money prize a bronze medal will be given to the holder of the prize, and a second medal to the essayist who comes next in order of merit. Further information for the guidance of competitors may be obtained by addressing the Registrar of the college, Dr. Edward Liveing, London, England.

The Hospitals of New York State.—According to a law passed last year all corporations established for the purpose of giving medical and surgical relief must have their certificates of incorporation approved by the State Board of Charities before they can obtain the desired powers to act. The necessity of making inquiries concerning various bodies suggested to the members of the Board the desirability of an investigation of the existing hospitals in the State, for the purpose of determining their present condition and efficiency, how far they have accomplished the purposes for which they were established, and what communities are not supplied with hospital facilities. Dr. Stephen Smith, chairman of the committee appointed to conduct this investigation, has visited most of the hospitals of the State west of Albany. As one result of this investigation it has been found that some of the best conducted and best constructed hospitals are in the smaller towns, and some of the worst are in the larger cities. One of the most common faults is that the hospital is built in order to secure handsome architectural effects without much regard for the prevailing winds, sunlight, etc. It is suggested that there be created in the office of the State Board of Charities a bureau of information on the construction and management of hospitals. If there were such a bureau, where the plans of all the latest and most approved hospitals of this and foreign countries could be readily consulted, the errors of the past would be avoided, and improved designs would be suggested for the future hospitals of this State.

Dr. Emil Yung has been appointed Professor of Anatomy at the University of Geneva, to succeed the late Professor Carl Vogt.

Cholera in Japan.—It is reported from Japan that the number of cases of cholera in that country since the beginning of the present epidemic has been about 25,000. The disease has been of more than average virulence if it is true, as stated, that the deaths exceed 16,000, or sixty-four per cent. of those attacked.

The British Medical Association will meet next year, it is believed, in Eastbourne, the medical men of which place, seconded by the mayor and corporation, having invited the Association to come there.

Dr. Schimmelbush, whose work on the "Aseptic Treatment of Wounds" was recently reviewed in these columns, died in Berlin on August 2d, aged thirty-five. He was assistant to Professor von Bergmann, in the Surgical Clinic of the University of Berlin, and was looked upon as one of the foremost of the younger generation of German surgeons.

The International Medico-Legal Congress will be held in the United States court-rooms, in the Post-office building, in this city, on September 4th, 5th, and 6th. The chairman of the Committee of Arrangements is the Hon. Rastus S. Ransom, and the secretary, Clark Bell, Esq. Dr. Forbes Winslow, of London, is expected to be present to act as chairman of the Section on Insanity and Mental Medicine.

Dr. W. W. Cable, of Pittsburg, died at his home in that city on August 27th, aged seventy-two.

The American Electro-therapeutic Association will hold its fifth annual meeting in the council-room of the College of Physicians and Surgeons of Ontario, Toronto, Canada, on September 3, 4, and 5, 1895. The president of the association is Dr. A. Lapthorne Smith, of Montreal; secretary, Dr. Emil Heuel, of New York.

Dr. Maragliano's Impressions of the British Medical Association.—The Rome correspondent of *The Lancet* quotes an interview with Professor Maragliano, of Genoa, by the London representative of *Il Secolo*, to whom he expressed his high admiration of the sanitary institutions, the hospitals, and the whole hygienic organizations of the British capital. He was surprised at the solidarity prevailing among the British medical men, at their well-disciplined meetings, at the practical sense which guides them, not only in the field of science, but in that of professional interests. The admirable organization of the meeting itself elicited his special commendation, its hospitality being beyond the hopes even of the exacting. The scientific discussions he found impressed with the gravity proper to the practical genius of the race, and while he missed the enthusiastic outburst of his southern compatriots he remarked the great attention in following the scientific discussions and communications.

Punishment for Selling Skim Milk.—Complaint was made not long ago that persons arrested for selling watered milk in this city were let off without adequate punishment. The complaint seems to have been heeded, for two milk-dealers received a few days ago sentences of a $50 fine and ten days' imprisonment, instead of the $25 fine usually imposed for selling watered and skimmed milk. A few such sentences as these will go far toward preventing the sale of adulterated milk in New York.

A Sociedade de Medicina e Cirurgia da Bahia is the name of a society founded recently in Bahia, Brazil. Dr. Pacheco Mendes is the president, and Drs. Braz do Amaral and Cerqueira Lima are the secretaries of the society. The organization publishes a monthly volume of transactions under the direction of Dr. Juliano Moreira.

The Index Medicus will probably be revived, at least it is hoped that the subscriptions will reach the requisite

two hundred before December 1st next. In addition to the subscriptions received by the publisher, Dr. Billings had received forty-eight up to August 23d. These subscriptions are conditional upon the obtaining of two hundred before December. It is hoped that when the physicians return from their summer vacation the desired number will quickly be obtained.

Eighty-two Physicians from the United States and nine from Canada were registered as guests and visitors at the recent meeting of the British Medical Association.

Miss McFee, of Montreal, has just obtained the degree of Doctor of Philosophy at Zürich. She is a graduate of McGill University, and studied Philosophy at Cornell and under Professor Wundt of Leipzig.

A New Explanation of the Bicycle Face.—A writer in the *Christian Intelligencer* says that the true explanation of the bicycle face has not yet been given by the doctors, who have themselves "fallen in with the unbelief and recklessness of the times and do not insist in their spoken and written words upon the need of one day of rest in every seven." This explanation is to be found in the habit of wheeling on Sunday. "Is it not possible," the *Intelligencer* asks, "that the law of the Decalogue is binding upon bicyclists as well as upon other people, and an habitual violation of the law of the Sabbath may result in the worn, weary, and exhausted face called the bicycle face? The bicyclists are doing much to destroy the Sabbath, and at the same time are injuring their own bodies and souls. The bicycle face, indicating extreme weariness and exhaustion, due to the severe strain of violent exercise on seven days of the week, will be followed, as surely as the Decalogue is the law of God, with moral weariness and exhaustion in the wheelmen and in those influenced by them." On the other hand, a French physician, who is himself a wheelman, maintains that the greatest benefit from this form of exercise can be obtained only by cycling every day regularly. Those who wheel every day can do so without causing excessive action of the heart, whereas those who ride only once or twice a week do so at their peril, the unwonted exercise causing a tumultuous and rapid action of the heart that may have very serious consequences.

Water-supply of Cleveland.—The Ohio State Board of Health has refused the petition of the City of Cleveland to be allowed to discharge sewage from a new district into Lake Erie near the intake of the city water-supply. Mr. Allen Hazen, of Boston, was employed by the Board as consulting engineer. Investigation showed that the water-supply is already polluted, and statistics revealed that the typhoid death-rate for the past seven years has been higher in Cleveland than in any other large city of the State. Plans for extending the intake into the lake are under consideration; but Secretary Probst is of opinion that, while this may afford a temporary remedy, all the lake cities will eventually be compelled to resort to filtration for the purification of their water-supplies. A better way would seem to be to prevent pollution by a proper disposal of sewage.—*Journal of the American Medical Association.*

Obituary.

WILLIAM C. JARVIS, M.D.,

NEW YORK.

Dr. William C. Jarvis died at Willet's Point, N. Y., July 3d. He was born in 1855 at Fortress Monroe, Va., where his father, the late Surgeon N. S. Jarvis, U. S. A., was stationed as post surgeon. After the death of his father in 1862, Baltimore became his home. He studied medicine at the University of Maryland, graduating at the age of twenty years. He then devoted a year to the study of chemistry and biology at the Johns Hopkins University.

In 1877, considering New York the most promising field for a young doctor, though almost an entire stranger here, he commenced practice in the eastern section of the city. After a year devoted to general medicine, he adopted laryngology as a specialty. Dr. Jarvis's success as a laryngologist was not surprising with his peculiar inventive powers. Of the numerous instruments contributed by him to nasal and throat surgery may be mentioned, *inter alia*, the Jarvis snare, in which the value of piano-wire for cutting purposes was first demonstrated, and by means of which morbid growths, whose removal by older methods necessitated painful and ghastly operations through the face, are eradicated easily and almost painlessly. The many modifications of this little instrument have in themselves proven how valuable was the principle. The laryngeal applicator, intended for the employment of fused crystals of chromic acid, in accordance with a plan conceived by himself, the ring speculum, and the operating nasal speculum are probably the best known of his additions to the armamentarium of the laryngologist.

By temperament and inheritance an indefatigable student, Dr. Jarvis was proficient in French and German, and he retained also his knowledge of the Latin and Greek classics. In his many contributions to medical literature Dr. Jarvis labored conscientiously to avoid a spirit of exaggeration and to submit only facts which he had proven by extensive personal experience of real value. Among his contributions to medical literature are several chapters on the throat and nose in well-known text-books. At the age of twenty-six he was invited to occupy the chair of laryngology at the University of New York. He was at that time barely acquainted with the members of the faculty of that institution and was told by the late Professor Loomis that he had been selected simply and only because he was considered the man qualified for the place. That Dr. Jarvis was a rare diagnostician, operator, and therapeutist it is needless to add.

Nor was his knowledge of medicine cramped by the selection of a specialty; he was a faithful student of general medicine, thoroughly aware of its value in the practice of a special branch.

At the time of his death Dr. Jarvis, by reason of ill health, had become Emeritus Professor of Laryngology at the University of New York, and consulting physician to the City Hospital. He was a member of the American Laryngological Association, a fellow of the Academy of Medicine, and a member of other medical societies.

The most interesting feature of the man, however, was his personal character. His was a type of the Christian, which all men, however sceptical, were compelled to admire. He was a true philanthropist; though fighting with all his energies unworthy appeals to the charitable, he gave liberally, and worked joyfully for the deserving poor and afflicted. Withal a modest, unpretentious man, a true friend, of a generous, open-hearted loving character, the medical profession and the community have sustained in his taking away a severe loss.

Clinical Department.

ANENCEPHALOUS MONSTERS.

By ALBERT C. BOWERMAN, M.B.,

PICTOU, ONT.

It may be inferred from recent reports in the MEDICAL RECORD that the "anencephalous monster" continues the invasion of the present race with a regularity heretofore unsuspected; but from the brevity of its individual existence, it may safely be conjectured that its advent is premature, being in the experimental stage of its evolution, for its short-lived appearance could scarcely be explained on the ground of atavism. Does the frequency of its repetition, under remote and dissimilar conditions of life, suggest the possibility of a design on the part of nature to meet impending necessities by anatomical reconstruction?

The absence of cerebral development, coupled with a good physical organization, might not unreasonably imply that, with the specialization of occupations, our race is fast becoming an aggregate of automata to whom, or to which, a cerebrum will be superfluous and possibly a source of inconvenience. Nature may be congratulated on having already achieved remarkable successes in this direction; and on the grounds of experimental research she may be excused for her prodigal waste of energy in the perpetuation of useless survivals. Viewed from the stand-point of the contemporaries of the cave-bear, the present race may not unreasonably be stigmatized as monstrous; while from our own point of view the evolving cyclist will represent a readjustment of anatomical parts too curious for conception; so that it is, at least, not generous to rashly criticise the subject of our pen-sketch without first being made acquainted with the peculiar sphere she was intended to fill. That there was a miscalculation in the time and an error in judgment in the selection of a place for her *début*, is conceivable from the rapidity with which her exit followed upon the heels of her unfortunate advent; but if we are to gain any information from the parental environment, we may presume that her sphere was at least semi-aquatic, as her birth occurred at a barren sand-lot on the borders of a marsh. However, be this as it may, on the evening of November 2d last, I was called to attend the wife of a laborer, said to be in the eighth month of her second pregnancy, and suffering for some hours with labor-pain. She was twenty-four years of age, and about two years before had given birth to a living child, normal in appearance, which, however, died at about ten months of some cerebral difficulty. For some weeks the patient had suffered from the weight and distention of what was not unreasonably suspected to be a multiple pregnancy, but which proved ultimately to be an excess of amniotic fluid. She was restless and sleepless, suffering from dyspnœa, and the common "nagging" pains of early labor. Examination revealed a slightly dilated os uteri. Nothing more unusual occurred until December 7th following, when I was again called. I found her much exhausted from hemorrhage, having been delivered some hours previously of a living "anencephalous" female child, which the nurse assured me had lived and breathed for nearly an hour. The body and limbs were fairly developed, though somewhat disproportioned, and the weight would be about three pounds. The limbs, especially the lower, were extremely long, giving the body a shortened and truncated appearance. It was, so to speak, curtailed at the head, and was entirely without even the suspicion of a neck, so that it was a reasonable subject for electrocution. The prominence of the chin occupied the sternal notch; and the ears, which were well developed, lay behind and rather below the shoulder-joints; the face, which was well formed, though not exactly interesting in the usual sense, was directed upward; and the eyes, exceedingly prominent from the lack of frontal bone, were disposed as a lookout in the rear. There is no doubt but that an eye at the back of the head would often gather unsuspected information, but when it is furnished at the expense of the usual position, the advantages and disadvantages are counterbalanced. Behind and between the ears was a fringe of dark hair on either side of the posterior median line corresponding to the occiput; but the cranium, if any, was open in the latter region, and continuous with the unclosed spinal canal as far down as the lower lumbar vertebra. Protruding from the upper end of this canal, and overlapped by the fringe of hair, were the congested lobes of the cerebellum, much enlarged and exposed across the dorsum almost to the base of the sacrum, and too large to be admitted into the limited room of the cranium. The length of back, from occiput to sacrum, could not have been more than three inches, so that the child had the appearance of a crescent with the hollow at the back.

By G. R. HINMAN, M.D.,

CHESANING, MICH.

In the MEDICAL RECORD for April 20th was the report of a case of anencephalous monster by Dr. R. H. Fillmore, of Cookshire, P. Q., Canada. And again another case quite similar reported by Dr. J. E. Tompkins, of Fredericksburg, Va. The following case, read in connection with those above mentioned, may possibly be of interest:

On the evening of March 2, 1895, at 8 o'clock, Mr. T—— called me to see his wife, whom I found suffering pains of no regularity and not of the true labor type. Her age was about twenty and she was a primipara. As she was only at the end of the seventh month of her pregnancy I endeavored to quiet the pains by viburnum, morphine having been given by another physician without effect.

I remained with the patient till midnight. When I left she had been sleeping about two hours and her pains were completely subdued. Examination had revealed a soft, patulous os, but there had been no hemorrhage.

At 6 A.M. I was again summoned and found the woman having pains quite regularly and of the true labor type. I therefore concluded that my attempts to forestall the issue were impossible, and assuming the expectant attitude, awaited results. Labor progressed slowly until the bag of waters ruptured. The membranes were extremely tough, and I delayed rupturing them, as my patient was very nervous and the bag was acting the part of a dilator. After the bag had ruptured the pains became more powerful, and my next examination revealed the presence of something unusual. I informed the father that we had something, but what it was I could not tell. The sensations felt by me on examination were like feeling of a substance hard as a stone and of irregular surface. Labor proceeded well and at about 6 P.M. on the same day a monstrosity came to light, dead. The mother said she had felt no motion for two or three days previous. The weight of the fœtus was about five pounds, skin tan color or brown, large bulging eyes, broad flat nose, mouth open, tongue protruding, os frontis flattened and receding; diameter of head, biparietal, two and one-half inches. On examining closely I found no sexual organs and no anus; but there was a black substance upon the right side of nates, upon removing which I found a small opening or orifice, evidently the bowel outlet. At the base of its skull was an opening large enough to admit the end of my little finger; from that a little blood was oozing.

The above case is entirely unique with me. The mother, so far as I know, is well and healthy, nothing that can be attributed to her in any way bearing upon the etiology of this monster. Her husband is choreic, has head-jerk, produced, it is said, as the result of a maternal impression, his mother, I am told, having been frightened by a snake.

By JOHN W. S. McCULLOUGH, M.D.,

ALLISTON, ONT.

Mrs. C——, aged thirty-two, II-para, was taken in labor at seven months. She is a very stout woman, five feet six inches in height and weighing 210 pounds. I saw her shortly after labor began and found the cervix dilated to the size of a quarter-dollar. The edges were sharp, hard, and inelastic. Gave three twenty-grain doses of chloral hydrate at intervals of fifteen minutes, and had the satisfaction of soon finding the cervix soften very materially. The presentation was difficult to make out, but I was convinced from the bimanual examination that I had an occipital presentation of some kind. The pains were very strong, but progress was slow. After the os was thoroughly well dilated I felt satisfied that I had a dead fœtus. I ruptured the membranes and delivery was soon complete. I immediately expressed the placenta. The hemorrhage was very trifling.

The fœtus measured fifteen inches. The nails were developed, as also were the eyelids; the eyes were open. There was a hare-lip. The fœtus was a male, the testicles had not descended; the limbs and body of the child were perfect. The placenta was almost entirely in a state of fatty degeneration. I am of opinion that the condition of the placenta accounts for the non-development of the fœtus.

Cor. Victoria and Ontario Streets.

Surgical Suggestions.

Indications for Induction of Abortion.—*Absolute Indications:* 1. Uncontrollable vomiting of pregnancy. 2. Incarceration of the gravid uterus. 3. Obstruction of the pelvic outlet by tumors or exudates. 4. Progressive and pernicious anæmia. 5. Grave chorea.

Relative Indications: 1. Great contractions of the pelvis with the conjugata vera below 5 ctm. 2. Pulmonary emphysema with signs of degeneration of the heart. 3. Nephritis, especially with eclampsia. 4. Chronic heart disease. 5. Other general diseases of the mother which jeopardize her life at the time of delivery.

A conjugata vera of 6 ctm. and advanced pulmonary tuberculosis should not be regarded as indications for abortion. It is not just to sacrifice a future life for one that is "certainly lost." —Jeffe.

Fistula in Ano.—1. Never sever the sphincters at more than one place at the same operation, no matter what the complications may be, otherwise incontinence is sure to follow. 2. Unless all the channels are followed up and laid open, the operation will fail of its purpose. 3. Fistula resulting from tubercular abscess must not be operated upon if there is sufficient tissue-destruction of lung to produce hectic, fever, sweats, etc., unless the fistula is causing severe painful spasms of the sphincters; then it should be divided at any stage. 4. After laying the fistula tract open the wound must be made to heal from the bottom, and as the cutaneous or mucous side of the wound is better nourished it will throw out a more healthy granulation, that tends to bridge over and close the slower granular surface at the bottom, thus leaving a fistula remaining. 5. When the fistulous tract is not too complicated it should be dissected out entire, and the wound brought together, beginning at the bottom, with continuous catgut sutures and approximating the surfaces in successive layers until the whole wound is closed. —Bacon.

Diagnosis of Rupture of the Intestine After Contusion of the Abdomen.—1. The absence of liver-dulness (Moritz). 2. Frequent and uncontrollable vomiting. 3. The appearance of peritonitis, if lesions of the kidney, bladder, liver, and spleen can be excluded. 4. Spontaneous pain in the abdomen is not of itself of much diagnostic value.

Regarding the advisability of operating in these cases, the author says: 1. If there is unmistakable evidence of rupture of the intestine, immediate laparotomy is indicated. 2. Exploratory laparotomy after contusion of the abdomen is usually to be avoided; in uncertain cases, expectant treatment should be adopted (Moty). 3. If soon after the injury (twenty-four to thirty hours) there are signs of sepsis, operation is contra-indicated. A low temperature with marked constitutional symptoms is an especially unfavorable condition. 4. Rapidity and delicacy are essential in operating for rupture of the intestine, especially if peritonitis is present. Therefore, a long abdominal incision, rapid, systematic examination of the intestine, avoiding rough tearing or handling; if possible to avoid it, do not resect the intestine; employ simple Lembert sutures, or at most a wedge-shaped resection of the injured portion of intestine, and close with a simple running suture including the muscular and serous coats. Flushing the abdominal cavity with antiseptic liquids is to be avoided. —Berndt.

Gonorrhœal Immunity. — 1. Gonorrhœa is a self-limited disease, recovery following after a varying length of time, without any treatment other than ptisanes, baths, and hygiene. 2. Abortive treatment does not succeed rapidly and fully until the period of acute inflammation has passed. 3. A patient, either male or female, apparently, though not really cured, is capable of transmitting a subacute gonorrhœa—that is, the colorless drop of secretion is capable of inoculation if it contains a few gonococci. The author consequently believes that the gonococcus during its evolution modifies its culture media, *i.e.*, the urethral mucous membrane. It continues to grow there but becomes more and more attenuated and latent, until it finally disappears. Unless this is true, a gonorrhœa, untreated, would last indefinitely, the cocci multiplying and re-inoculating themselves in the infected urethra continuously. It is at the time when the virulence begin to diminish that abortive treatment succeeds. If, on the other hand, this attenuated gonococcus comes in contact with a healthy mucous membrane in another individual it is immediately rejuvenated, prospers, and produces acute gonorrhœal symptoms, since it finds there a suitable culture medium, which is not exhausted with that from whence it came and where it was about to die. The objectors to this theory say: "If you admit that the *rôle* of the culture-medium is thus superior to that of the microbe, how can you explain acute attacks in men having gleet? How can their exhausted mucous membrane become re-inoculated?" Guiard believes this re-infection is impossible in cases where the gleety discharge contains cocci. He, however, reserves his opinion regarding this form of relative immunity until further facts are procured.—Jamin and Guiard.

Indications for Resection of Skull.—1. — We are called to make a resection in complicated fractures, when it is feared that infective matter has entered the wound, or when it is known that the cranial cavity has been penetrated by some dirty knife or instrument. 2. In fractures to which an unclean dressing has been applied. 3. When we suspect a fracture of the inner table or for depressed fractures. 4. For the removal

of foreign bodies, bullets, knife-blades, etc. 5. For cerebral hemorrhage, with signs of compression, and for the ligation of the middle meningeal artery. 6. For fractures which have subsequently become infected through carelessness on the part of the surgeon or attendant. 7. For tumors of the brain, abscess of the brain, epilepsy, and chorea, when due to trauma, syphilis, and tuberculosis.

Auto-inoculation of Chancre.—In the first case the seat of the chancre was inoculated in the right armpit; in the second, the chancre was on the inner side of the eyelid, which the patient had rubbed continually, a particle of iron shaving having lodged in the conjunctival cul-de-sac; in the third, it occurred in the folds of the prepuce.—Nolin.

Therapeutic Hints.

Pityriasis Versicolor.—

℞ Cold cream ..... ℥ j. ½
Unwashed precipitated sulphur ..... ℥ j.
Iodide of sulphur ..... ℥ ½
Red oxide of mercury ..... gr. 15½

Rub in well three times daily, then dust with a powder made of talc and starch.

—*Mouvement Thér. et Méd.*

Cholera Infantum.—

℞ Naphthalini ..... gr. xx.–lxx.
Ol. bergamii ..... gt. i.–ij.

M. et ft. chart No. XII. Sig.: One powder every two or three hours.

—Holt.

℞ Tr. opii deod ..... gtt. xvi.
Spt. ammon. aromat ..... f ℥ i.
Bismuth. subnit ..... ℥ ij.
Syr. simp ..... f ℥ iv.
Mist. cretæ ..... f ℥ iss.

M. Sig.: Teaspoonful every two or three hours for a child of one year.

—J. Lewis Smith.

Hyperemesis.—

℞ Cocain. chlorohydrat ..... gr. iss.
Antipyrine ..... gr. xvi.
Aquæ destil ..... ℥ iv.

M. Sig.: ℥ i. every half hour until relieved.

—Lutaud.

Dysentery.—

℞ Pulv. ipecac. co ..... gr. vi.
Bismuth. subcarb ..... ℥ i.
Pulv. aromat ..... gr. vi.

M. et ft. chart No. XII. Sig.: One powder every three hours for children.

—Starr.

Croup.—

℞ Acid lactici ..... ℥ iijss.
Aquæ destil ..... ℥ x.

M. Sig.: Apply often by means of a spray-producer (to dissolve false membrane).

—Morell Mackenzie.

Alopecia after Acute Diseases.—

℞ Alcohol ..... ℥ viss.
Veratrine ..... gr. viss.
Tinct. benzoin ..... gtt. xv.
Salicylic acid ..... gr. viss.

M. Sig.—Apply locally.

—Kaposi.

To Lubricate Catheters.—

℞ Bichloride mercury ..... gr. i.
Glycerin,
Water ..... āā ℥ ij
Powdered soap ..... ℥ iv.

M.

This ointment is claimed to be unirritating to the urethra, and to possess greater lubricating power than either oil or glycerin.—Guyon.

Society Reports.

THE BRITISH MEDICAL ASSOCIATION.

Sixty-third Annual Meeting, held in London, July 30 and 31 and August 1 and 2, 1895.

(Specially Reported for the Medical Record.)

SECTION OF OBSTETRIC MEDICINE AND GYNECOLOGY.

First Day, Wednesday, July 31st.

Address of the Chairman.—Sir William Priestly delivered a short inaugural address, in which he drew attention to the enormous advances which had been made in midwifery practice, especially those due to the application of antiseptics in midwifery. Whereas in a lying-in hospital with which he was connected the mortality was 34 per 1,000 before the introduction of antiseptics, since that epoch it had been only 2.5 per 1,000. And in addition to the saving of life there was a much lessened morbidity during the puerperal period. Although there was so great an improvement in lying-in institutions, yet the mortality in private practice had not diminished to the same extent, therefore the discussion which had been arranged for that morning.

Other improvements were those in forceps, and especially the introduction of the axis traction forceps, which allowed of delivery in cases in which it was previously impossible.

Modifications also in craniotomy instruments had rendered that operation easier and safer.

But the greatest advances had been in gynecology. He could recollect the time when tapping was the only remedy for ovarian tumors, and a promise of five years of life was the longest that could be given to a patient with such a tumor. A great surgeon of that day had said that he considered the man who attempted the complete removal of an ovarian tumor guilty of manslaughter. The speaker had lived long enough to see several different systems of treatment, enthusiastically advocated, have their day and then wane away. First there was the craze of ulceration of the os as a cause of most of the ailments of women, and the treatment of these ulcerations by caustic, etc.; then clitoridectomy loomed up as a treatment, but was soon discredited; after this displacements of the uterus held the field, and mechanical treatment ruled the day; again there was an epoch of enthusiasm for castration as a cure for many neuroses; ere long it was discovered that the operation was followed by worse nervous symptoms than those for the relief of which it was undertaken; then rents of the cervix were thought to be the cause of symptoms in so large a proportion of cases that one gynecologist discovered and operated on three hundred torn cervices out of nine hundred women examined by him; lastly, there had been an epidemic of the operation for the removal of the appendages. Many of these recommendations had come from across the Atlantic. No doubt each of them had some value, but the tendency now was to import too large a surgical element into the treatment, and to neglect the medical side of gynecology. We must consider the welfare of our patients first and the science of surgery second. The records of one thousand operations had no intrinsic value unless the operations can be shown to have been necessary, and he especially deprecated the efforts to make long lists of operations. He would entirely discountenance large operations for uterine fibroids which were not producing symptoms; also the operation of opening the abdomen for the treatment of displacements of the uterus; considered the views he had expressed were those of real as against spurious progress, and he was willing to receive any help from new ideas and operations, but

would always bear in mind the motto: *Primo non nocere* (at least do no harm).

Dr. Priestly deprecated the tendency of the obstetric physician to invade the domain of surgery and thought that sepsis was more likely to be acquired in the work of the surgeon, and he would advise obstetric physicians to keep to their own art. He would in general hospitals appoint a surgeon to act with the obstetric physician, and in special hospitals would have physicians to consult with the surgeons, but each man should take his own course.

Dr. Lusk, of New York, in proposing a vote of thanks, said that he thought the address would do good in America, and that he agreed with the President's views.

The vote of thanks was seconded by Dr. Martin, of Berlin, and carried with acclamation.

The Aseptic and Antiseptic Precautions Necessary for the Prevention of Puerperal Fever in Private Practice.—Dr. G. Ernest Herman, of London, opened the discussion on this question. In answer to the question, What is puerperal fever? he said that it is a fever caused by the inoculation of septic organisms. Septic organisms are not the same as saprophytes (which in our climate are everywhere present), but may in suitable soil be bred from saprophytes. They only thrive in special soil, and they can and ought to be destroyed. Sterilization, that is the destruction of *all* micro-organisms, is impracticable in midwifery practice. Puerperal fever may be prevented by keeping septic germs from the patient. This is to be done by asepsis, that is cleanliness, and antisepsis, that is the use of germicides. The germicide which is the most portable and most trustworthy, and therefore the best for midwifery practice, is corrosive sublimate. Carbolic acid is inconvenient, and no other antiseptic has been shown to be so good clinically as perchloride. The precautions to be used are of two kinds: 1, External, those applied to the surroundings of the patient; 2, internal, those applied to the patient.

The external antiseptic precautions comprise the purification of each attendant's hands by washing with soap and water, using a nail-brush and soaking in a corrosive sublimate solution 1 to 1,000, and of all instruments by boiling; scrupulous cleanliness in the dress of nurse and medical attendant; the use of clean absorbent material instead of napkins and sponges. The nurse's dress should be light color, with washable apron and sleeves to turn up, attached by buttons. There should be no rings on the fingers. The internal aseptic and antiseptic precautions comprise restriction of vaginal examinations to the fewest possible; washing of the genitals; the use of an antiseptic lubricant; vaginal antiseptic douches during labor, after delivery, and throughout the lying-in. The only one of these precautions that can possibly do harm to the patient is the use of antiseptic vaginal douches. Experience has shown that healthy women whose labors are normal do as well without vaginal douches as with them, though these are necessary in some abnormal cases.

In private as compared with hospital practice there is less danger; therefore vaginal antiseptic douches before delivery and during the lying-in may be omitted, except in cases in which the discharges are unhealthy. An antiseptic douche immediately after labor is over should be given by the medical man himself. The nurse receives less guidance; she is not guided by rules as she is in a hospital. But such guidance is necessary. The medical man should make it part of his duty to the patient to instruct her nurse. Some physicians do this by giving the nurse a printed paper of directions. This practice is recommended for general adoption. The nurse is under less discipline. She is often chosen by the patient. The patient's wish is her law, for her success depends upon her pleasing the patient. The doctor should insist that the nurse obey him, that she be dismissed if she neglect his rules, and he should decline to be responsible for the case unless the nurse is engaged with this understanding.

Dr. Stuart, of Brooklyn, said that he had prepared a paper, but would not read it, as Dr. Herman had covered the same ground. He would emphasize the following points: First, that the physician himself should be thoroughly imbued with the principles of asepsis, and secondly, that he should instruct the nurse and make certain that she understands his instructions. The patient should be talked to and instructed as to what her dangers are. The physician should have clean linen, and should dispense as much as possible with the vaginal examination, using the abdominal instead.

Dr. Lusk, of New York, would first wash hands in alcohol and then in corrosive solution. He would cut the pubic hair and sterilize the perineum and inner surfaces of the thighs. He would not use a vaginal douche after a simple labor, and would strongly discountenance douching before labor, as nature thoroughly cleansed the vagina, first by the liquor amnii, and then by the passage of the fœtal head. He dwelt on the great importance of clearing away all clots and tissue, which might decompose. He would place some antiseptic material over the perineum before applying the hand to guide the head as it was emerging to avoid soiling the hand with fecal matter. He thought it important to wait long enough for the placenta to be detached; complete separation would be shown by the cessation of pulsation in the cord. There was no necessity to twist the membranes into a cord as advised by some; it was sufficient to allow the weight of the placenta to draw away the membranes.

Dr. Smyly, of the Rotunda Hospital, Dublin, said that it was not always necessary on the first visit to make a vaginal examination. The nurse should never be allowed to make a vaginal examination; and he thought the douche in the hands of a nurse was dangerous. He formerly douched each patient twice a day after confinement, but had now given up that plan as dangerous.

Dr. Swayne, of Bristol, drew attention to the fact that among the poorer classes the patients may infect themselves with their finger-nails.

Dr. Playfair, of London, regretted that practitioners were not so imbued with antiseptic principles that such a discussion should have been considered unnecessary. He had found it impossible to get nurses to use 1 in 20 carbolic solution for the hands, on account of its unpleasant roughening effect on the skin; but perchloride had not this disadvantage to the same extent. He attached most importance to the thorough scrubbing of the hands. He considered that douching during lying-in gave so much comfort to the patient that he would not say it should not be used. For this purpose Condy's fluid acted well.

Dr. Byers, of Belfast, would minimize vaginal examination as much as possible, and thought it was a great step forward to substitute abdominal examination, by which he considered almost everything necessary could be ascertained. In making a vaginal examination particular care should be taken to avoid contamination from the rectum, and he thought that some so-called autogenetic cases could be attributed to this cause. For two years he used a douche after delivery in each case; last year he abandoned the practice and had found no difference in the results. After the birth of the child he follows the Rotunda practice of turning the woman on her back for the expression of the placenta, as by so doing the entrance of air was avoided.

Dr. More Madden, of Dublin, considered it important to get the woman into a good state of health by tonics, etc., before delivery.

Dr. Murdoch Cameron, of Glasgow, thought there were two forms of puerperal fever—sapræmia with fetid lochia and septicæmia with suppression of lochia.

For the first, one could do a great deal; for the second, nothing.

Dr. Herman, in closing the discussion, said that he could not see the good of attempting to sterilize the perineum and thighs, since complete sterilization was impossible. Corrosive sublimate was the one germicide which had stood all tests. He would boil all instruments, including the vaginal tubes.

Electrotherapy as a Means of Diagnosis in Gynecology.—Dr. G. Apostoli, of Paris, presented a communication with this title. After a long and thorough trial of this method he had come to the following general conclusions: 1. The faradic current of tension (generated by the coil of long and fine wire) applied to the uterine cavity, according to the rules established by the speaker in 1883, relieves, for a longer or shorter time, all ovarian pain of nervous or hysterical origin; but it is powerless or nearly so in cases of ovarian pain caused by inflammatory lesion of the peri-uterine tissue or of the appendages. 2. The same faradic current is therefore useful in diagnosis, inasmuch as it helps us to distinguish the nature of so-called ovarian pain and to determine rapidly the differential diagnosis between hysterical and inflammatory ovarian pain. Where the two kinds of pain exist in the same patient we are helped to understand their nature by the fact that the one is relieved and the other is not. 3. If, then, the curative effect of the faradic current clears up or rectifies a doubtful diagnosis, it protects us at the same time from undertaking a useless operation. On the other hand, if the same faradic current proves ineffective, the lesion being inflammatory, we are led to resort to a supplementary galvanic treatment or to a surgical operation sooner or later. 4. The constant galvanic current, applied to the uterine cavity in doses gradually increasing from 50 to 120 milliampères, according to the rules published by the speaker in 1884, and bearing in mind the individual susceptibility and tolerance, will be almost always supported without much pain during the *séance*, and without febrile reaction afterward, if the parts adjacent to the uterus are free from inflammation. Simple cystic, peri-uterine tumors which are neither inflamed nor suppurating (such as ovarian cysts and hydro-salpinx), may also show perfect tolerance of the galvanic current. The galvanic current is also sometimes perfectly supported by cases in which the uterus is surrounded by old inflammatory products or exudations no longer pathogenic. 5. There are three classes of cases which should be considered as exceptions to the preceding rule, for they bear the galvanic current more or less badly, though they do not necessarily produce much febrile reaction after the *séance*. They are: *a*. Certain forms of hysteria. *b*. Fibro-cystic tumors of the uterus. *c*. Enteritis with false membrane. It is generally easy to diagnose these cases of intolerance. 6. All acute peri-uterine inflammation (of the pelvic cellular tissues, of the peritoneum, and especially of the appendages) will cause the galvanic current to be badly borne when it passes 40 or 50 milliampères, and will cause intolerable pain and febrile reaction when carried beyond this intensity. 7. The intolerance for the galvanic current is generally proportionate to the extent and gravity of the lesions referred to and increases with the intensity of the current employed, especially when it passes 40 or 50 milliampères. 8. All inflammation of the appendages which is curable without radical operation will bear the galvanic current better and better, and there will be a corresponding improvement of the prominent symptoms, such as pain and hemorrhages. The intolerance noted at the beginning progressively disappears. 9. All grave inflammatory lesions of the appendages, and notably all suppurative processes which are incurable by conservative means, show the same intolerance from the beginning to the end of the treatment which was noticed at first, and which is apt to increase instead of diminish if the treatment is continued. 10. Thus the simple study of the tolerance or intolerance of the intra uterine galvanic treatment, and especially of the post-operative pain and fever occurring on the evening of or the day following the treatment, enables us to make the diagnosis. It also, in four or five *séances*, given twice weekly, informs us of the condition of the appendages, of their possible inflammation and its degree, and in this way it lessens the number of laparotomies and exploratory incisions. 11. The same study of the so-called galvanic reactions also informs us, after a few trials, of the curability of these inflammatory lesions which the electric current has demonstrated, and in consequence of this it tells us in one case to abstain from operation while in another it shows an operation to be urgent. 12. Finally, gynecological electro-therapeutics, carefully, methodically, and patiently applied, instead of being opposed to the marvellous progress of surgery, comes to its aid. Independently, in fact, of the great therapeutic service which it renders every day, electricity assists us in diagnosis and thus directly serves the interests of surgery, in one case showing an operation to be useless and dangerous, in another that its necessity is urgent. Many laparotomies, so-called exploratory incisions and mutilations practised without due deliberation for the relief of rebellious ovarian pain or for lesions of the appendages of uncertain nature, should be delayed until all the resources of faradic sedation, on the one hand, and of the intra-uterine galvanic effect, on the other, have been tried. Experience has abundantly proved these currents to be innocuous if given with necessary aseptic precautions.

Dr. Franklin Martin, of Chicago, had worked for ten years at the Woman's Hospital, using both electricity and surgery, and so was not biassed either way. He found it a fact that pain was produced and electricity was not well borne when collections of pus were present. He did not believe, however, that it should be used as a diagnostic agent, and it was very dangerous, and should not be used when pyosalpynx was suspected.

Gonorrhœa in Women.—Dr. More Madden, of Dublin, read a paper on gonorrhœal infection in some of its gynecological aspects. He thought that the importance of gonorrhœa was not yet fully recognized. Most cases in married women were due to a recrudescence of an old injection in the husband. He did not consider that the presence or absence of the gonococcus was an infallible test, as other cocci almost indistinguishable were found in the vaginal secretions, and he would treat all suspicious discharges at once by the free employment of germicides.

Dr. Purslow, of Birmingham, thought that everyone engaged in hospital practice must agree as to the great importance of gonorrhœa as a cause of disease of the uterus and appendages, but it was not often possible to follow cases through from the onset of infection. He had had two cases under observation for two years. Each became infected with undoubted gonorrhœa when pregnant and afterward aborted. They were treated with injections of perchloride of mercury, and up to the present there was no disease of the appendages. He asked whether any of those present had tried the active treatment of gonorrhœa by thorough disinfection of the vagina under anæsthesia.

Dr. W. Japp Sinclair, of Manchester, said that he considered the gonococcus of no use as a diagnostic sign. He considered that inflammation of Bartholin's glands was the most important clinical sign of acute gonorrhœa.

Dr. W. S. A. Griffith, of London, thought there was an undoubted gonorrhœal vaginitis, and that the disease was not always confined, as some held, to the urethra. He had treated cases in the way Dr. Purslow had mentioned. He placed the patient in the lithotomy position, used a speculum, and swabbed out the vagina very thoroughly, then dried it and dusted with iodo-

form, and afterward kept the surfaces apart by a simple dressing, which latter he removed in twenty-four hours and followed up by simple douching.

Surgical Treatment of Puerperal Fever.—Dr. James Murphy, of Sunderland, read a paper on this subject. He narrated some cases in which he had curetted, and others in which he had performed abdominal section, and urged the application of each of these in suitable conditions.

Dr. Leith Napier, of London, would always use gentle curetting before doing an abdominal section. His experience of operating in suppurative peritonitis had not been so satisfactory as that of Dr. Murphy.

Mr. J. W. Taylor, of Birmingham, had found operation successful when there were limited collections of pus, but when there was general peritonitis it was no good.

Dr. Lusk, of New York, thought curetting of a parturient uterus was the most mischievous practice ever introduced into midwifery practice.

Dr. Griffith, of London, thought few cases were suitable for curetting, and that it was a proceeding which had been much overdone. It was a dangerous operation, and he had known very severe bleeding follow from the opening of the uteric sinuses by the curette. He thought that in some cases the finger would remove any retained matter better than the curette, and that then washing out was followed by good results. There were many cases of puerperal pyrexia in which no sepsis was present.

Second Day, Thursday, August 1st.

Anterior Colpotomy.—Dr. Martin, of Berlin, read a paper with this title. He first pointed out the disagreeable results which followed an abdominal section, especially those resulting from the presence of the scar. Of late years there had been a great advance in vaginal surgery, and the best entrance into the abdominal cavity from the vagina was through the anterior fornix; there were no organs and no vessels in the way. The bladder can be separated and pushed up without danger and the ureter can be pushed out of reach.

Description of the Operation.—Patient is placed in lithotomy position and the uterus fixed by a special pair of forceps which combines both a probe and a vulsellum. Another pair of vulsella is fixed into the vaginal wall over the urethra and the vaginal wall is raised and incised vertically. The upper portion and bladder is pushed up with the finger and carried out of the way behind the symphysis. The peritoneal fold between bladder and uterus is then seen and is opened. There is very small loss of blood during this part of the operation, no pressure forceps or ligature being required until the peritoneal cavity is opened. After the operation the uterus and adnexa are replaced and catgut sutures passed through vaginal wall, peritoneum, uterine tissue, and back through vaginal wall again.

This operation was suitable for myomatous tumors wherever situated, and large tumors might be removed in this way by morcellement.

Total extirpation of the uterus could be performed, retroflexed uteri could be fixed, and peritoneal adhesions could be broken down. In procidentia he excised part of the vaginal wall and fixed the uterus to the upper part. Cystic ovarian tumors could be brought down and the pedicle seen and ligatured. In diseases of the tubes the operation had special advantages, and he had done it in tubal pregnancy. In cases of distended tubes the tube could be opened and drained and the opening fixed to the edges of the wound. The speaker had performed anterior colpotomy in 109 cases; all had recovered. The minority had required the use of the catheter after operation; in four of these operations he had done total extirpation of the uterus. For myomata he would prefer abdominal section when the tumor was larger than the size of two fists.

Vaginal Cœliotomy.—Mr. J. W. Taylor, of Birmingham, read a paper advocating this operation. He drew attention to the advantages of the utero-vesical pouch for the operation. The uterus may be anteverted and both it and the appendages inspected. Vaginal fixation of the uterus in this operation places it in a more satisfactory position than that by any other method. In doing vaginal hysterectomy the uterus was anteverted and brought out and forceps applied to the broad ligament from above downward. Doyen originated this method. He (Taylor) made a transverse incision in anterior fornix, passed a provisional silk suture through uterus as high as he could reach; if vaginal fixation only was required, he passed silkworm gut sutures through uterus and vaginal wall. Apart from vaginal hysterectomy he had done this operation seven times and he was satisfied with its value, especially for retroflexion incurable by other methods. He removed the sutures which he used for fixation in six weeks and left no buried ones. The operation was more difficult than abdominal section, but the advantage to the patient was decided, and recovery was more sure; then there was no visible scar resulting and no risk of hernia. He differed from Martin in making a transverse instead of a longitudinal incision.

Dr. Donald, of Manchester, read a paper on a case of vaginal cœliotomy for tubal pregnancy. He opened the peritoneal cavity through anterior fornix.

In the discussion which followed on these three papers, Dr. Cushing, of Boston, said that in these operations a process of evolution was always going on. He did not use a single long forceps, as he was afraid that the upper part of the broad ligament might not be secured, and he preferred to put on two or three smaller ones on each side. He had known a blade of the long clamp snap twelve hours after operation. In bringing down the uterus, if he were not going to remove it, he would avoid as much as possible the provisional ligature and the vulsellum. He preferred a vertical to a transverse vaginal incision because there was, 1, less hemorrhage; 2, more room. There was a danger of including ureters in the sutures when they were put in transversely and too freely; he thought that the separation of adhesions was easier than when abdominal section was done, and no drainage-tube was required.

Dr. Smyly, of Dublin, had done the operation about twenty times, and he considered that for fixation of the uterus it had great advantages over abdominal section, or Alexander's operation; at first he did fixation without opening the peritoneum, but he found the displacement recur; he now opens the peritoneal cavity; the most satisfactory results he had had from the operation had been in cases of prolapse.

Dr. Walten, of Manchester, had operated on two patients, who had previously been operated on by abdominal section, and the patients expressed appreciation of the vaginal method as compared with section. During the operation, an assistant should introduce a finger into the rectum and push up the uterus.

Dr. Alfred Smith, of Dublin, asked, How would a wound of intestine caused by separating adhesions be treated when the operation was performed in this way?

Dr. Martin, in closing the discussion, said he had never met a wound of the intestine in all his cases, though he had had to deal with severe adhesions, but his custom was to pull the organs out gradually and see the adhesions before dealing with them. If the uterus were adherent to the sacrum, he would not do cœliotomy. He would open the anterior in preference to the posterior fornix, because the tubes were nearer and the uterus could be more easily dealt with in the former incision. He had found cases in which both tubes needed removal were a minority of the total cases he had operated on, and he would preserve one

tube and the uterus whenever possible. Hydrosalpynx did not need removal, he would prefer salpyngostomy. He preferred the vertical to the transverse incision, because the latter was liable to be extended by tearing, and the ureters might be injured. He used catgut for nearly all his work now, and seldom used silk or silkworm-gut.

The Management of Girls at the Period of Puberty.—Dr. Playfair, of London, read a paper entitled, "Remarks on the Education and Training of Girls at and about the Period of Puberty." Up to puberty there was no necessity to treat boys and girls differently. At puberty well-defined changes occur in the girl, and there was an especial development of the nervous and emotional system. With limitations essential to sex, he considered that the advent of the higher education of women was an advantage. The fault of nearly all who managed high schools was that they ignored the sexual functions of the girls, and that they contend that there was no real difference between the adolescent male and female. If that were so, how is it that we see so many cases of anæmia in the adolescent girl, and the disease is almost unknown in boys? One reason is that in boys' schools physical sports are compulsory, while that is not so in girls' schools, and the tendency is for them not to take nearly sufficient exercise. Exercise should be compulsory in girls' schools, and another regulation he would like to see would be one to interdict corsets. He would insist on the importance of at once stopping all school work when symptoms of illness begin to show themselves.

Dr. Scharlieb, of London, would also make physical exercise compulsory. He thought that too many school-mistresses were absolutely blind to physical symptoms.

Dr. Gray thought that among no class of girls was the evil of overwork and insufficient exercise more pronounced than in pupil teachers.

Puerperal Eclampsia.—Dr. Swayne, of Bristol, read a paper on the "Treatment of Eclampsia Occurring during Pregnancy before the Commencement of Labor," in which he said that he placed most faith in venesection as a remedial agent.

Dr. Scharlieb had seen many cases in India, and there bleeding was not advisable, as many were anæmic. Had found chloroform give best results, putting the patient under it for each examination, and keeping her under it if the fits were frequent.

Dr. Smyly, of the Rotunda Hospital, Dublin, would not induce labor in these cases. Though chloroform stopped convulsions, he thought it increased deathrate. He would trust to morphia given hypodermically. He had observed no benefit from potassium bromide and thought pilocarpine dangerous.

Dr. W. S. A. Griffith, of London, would induce labor with the proviso that it were done safely and aseptically.

Dr. Barbour, of Edinburgh, had made frozen sections with a view to determine whether pressure of the uterus had any importance as a cause of the albuminuria which precedes the convulsions, and had come to the conclusion that, whatever the cause, it was not mechanical. Advised induction of labor.

Third Day, Friday, August 2d.

The Early Diagnosis of Malignant Disease of the Uterus, and the Treatment by Partial or Total Excision.—Dr. J. Knowsley Thornton opened the discussion on this subject, saying that he would give his own practical experience and views, not a summary of that of others. He appealed to those in general practice to take more note of trivial discharges, and departures from menstrual health, and above all in such cases to insist on an internal examination; it is in their hands, and not in those of the consultants, that advance in early diagnosis lies—if there is only suspicion have it at once either confirmed or dispelled by consultation with some specialist of experience. He detailed briefly the most reliable symptoms of cancer, but deprecated the removal of small portions for microscopical examinations, as he believed that interference of this sort often favored the growth of the neoplasm. He advocated supra-vaginal amputation of the cervix for adenoma and epithelial cancer of the vaginal portion; to remove the uterine body is useless in most of these cases. The speaker gave a brief description of the method of performing supra-vaginal amputation of the cervix and vaginal hysterectomy. He agreed with Williams that certain so-called recurrences were really fresh outbreaks, in a specially susceptible organ, and their bearing on the relative value of the two operations. As regarded the selection of cases he would deprecate operation in hopeless cases, and insisted on the application here of the sound surgical rule, that operations for malignant disease should only be performed when the whole disease can be efficiently and entirely removed. He defined cancer as a growth of epithelial cells with a tendency to invade tissue, and to break down and die. As to the after-treatment, he preferred light plugging with iodoform gauze, leaving the plug in for a week unless the temperature rises or discharge becomes offensive. After recovery, he advised careful examination every three weeks. Complete removal of the uterus may be effected by either vaginal or combined vaginal and abdominal operation.

The speaker would only do the latter when the vagina is too small or the uterus too large for the former operation to be possible.

In cases of vaginal extirpation he opened the peritoneum at front and back by pushing up a pair of Lister sinus forceps, and then enlarged the opening. He divided the broad ligament bit by bit, tying the vessels as they appear with silk, and he thought that in this way there was less danger of injury to the ureters than when the clamp was used. He did not use sutures for the peritoneal edges, and plugged lightly with gauze and removed it and used free douching on first appearance of any fetor or rise of temperature. He would not operate at all when mobility of the uterus was in any way impaired, nor when the vaginal wall was involved.

Dr. Martin, of Berlin, could not depend altogether on symptoms, and would only place absolute reliance on microscopic examination. He had found that even in some cases in which the growth was diagnosed at an early stage, and removed freely, it recurred, and did not think that the question of the advisability of operation on every case, even when discovered early, was yet settled. He did not believe in partial excision; no one would propose partial operation in cancer of the breast. In his own practice he had found that in all cases in which he had done supra-vaginal amputation of the cervix disease recurred, and he now always practised total extirpation. He did not operate when cancer had invaded the broad ligaments or glands, but he did not consider invasion of the vaginal wall a bar to operation, as that could be removed. He did not approve of some operations done lately, in which the sacrum was resected and the glands as well as the uterus were removed. A day or two before operation he removed any sloughing growth with the hot iron. The primary result of total extirpation was assured, with a mortality of four to ten per cent., but the secondary results were doubtful.

Dr. Pozzi, of Paris, said that total extirpation was the best operation, and was the one always practised in France. He thought that high amputation of the cervix was a bad operation, for in doing it hæmostosis was difficult, and in women not past the climacteric there was a possibility of stenosis of the cervix followed by hæmometra occurring, and he had seen three such cases. In France they used forceps. When the uterus could be easily drawn down the operation was a good

one, but when it could not it was a difficult and bad one. In cases unsuitable for radical operation, curetting, followed by the free use of the hot iron, not the Paquelin cautery, prolongs life.

Dr. Lusk, of New York, did not trust microscopical diagnosis, as different laboratories gave different reports on same specimen. In the treatment of incurable cases he found good results from scraping and packing with chloride of zinc, ʒ v. to ʒ j.

Dr. W. Japp Sinclair, of Manchester, thought that the greatest difficulty in differential diagnosis of early cancer was from hyperplasia of cervix associated with laceration and erosion of retention cysts. He did not believe in microscopical examination, and thought that the most important clinical test was that cancerous tissue was friable and would break down under a sharp spoon, while the other would not. He did not consider supra-vaginal amputation a suitable operation in women who had not passed the menopause. He used the ligature and did not pack wound, but put in drainage-tube.

Dr. Playfair, of London, placed no reliance on microscopical examination, and did not approve of partial extirpation.

Mr. Taylor, of Birmingham, had faith in the microscope. He thought, as a clinical sign, blood on the examining finger was one which should most excite suspicion. He advocated total extirpation.

Dr. Smyly, of Dublin, advocated the ligature. He always destroyed the cancer with the cautery before resorting to operation.

Dr. Spencer, of London, advocated amputation of the cervix. He believed some cases in which cancer of the body of the uterus had been said to exist were really not cancer. He considered cancer of the body an exceedingly rare disease. He had known pregnancy to occur in a case in which almost complete stenosis of the os followed amputation of the cervix. Cæsarean section had to be performed in that case.

Dr. Thornton, in closing the discussion, pointed out that the analogy with the breast does not hold, as the cervix and body of the uterus are different in structure; furthermore, cancer of the cervix seldom tends to invade the body. The life-history of cases of partial extirpation gave the best ultimate results.

Position of the Fœtus in Utero.—Dr. Murdoch Cameron, of Glasgow, read a paper entitled, "A New Theory as to the Position of Fœtus in Utero." This was based on observations made in the course of the operation of Cæsarean section, on the relative position of the dorsum of the fœtus and the placenta; these showed that the placenta and dorsum of the fœtus were on opposite sides of the uterus, thus in the first cranial position the placenta would be on the right side of the uterus posteriorly. Dr. Cameron's theory was that if the fœtus should be so placed as to bring its dorsum and the placenta in apposition, then the pressure to which the placenta was subjected caused partial asphyxia in the fœtus, and the latter changed its position so as to bring it into the relation described.

The Changes in the Uterus during the Third Stage of Labor.—Dr. Freeland Barbour, of Edinburgh, read a paper on this subject, his observations being based on the study of frozen sections. They showed that the placenta did not separate during the diminution in the size of the uterus which followed the birth of the child, and that there was no evidence of separation even when the uterus contained nothing else but the placenta. He had found no evidence of retro-placental hemorrhage. Frozen sections at the end of the second stage showed no separation of the placenta, contrary to the usual view. At the commencement of the third stage, the placenta was unseparated, even though the area of its site had been reduced to one-fourth. The clinical bearing of this was that patients never bleed until the second stage is over. The arrest of hemorrhage is caused by a complete rearrangement of muscular fibres; besides shortening, the planes of muscular fibres glide on one another, so as to make the path of the blood-vessel tortuous. Shrinking of the site is not the chief factor in producing separation of the placenta. One factor, no doubt, is the forcing out of the placenta by uterine contraction in the same way as the fœtus was forced out.

The Section was then adjourned.

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, April 24, 1895.

George P. Biggs, M.D., President, in the Chair.

Gall-bladder Containing a Large Calculus.—Dr. Donald M. Barstow presented a specimen that had been taken from a very obese woman, forty-eight years of age, who had been admitted to the New York Hospital on May 7th. She had given no history of biliary colic. She was anæmic and feeble, and suffered considerably from dyspnœa. She died on May 31st. At the autopsy the valves of the heart were found to be competent. There was slight stenosis of the mitral valve. The heart muscle showed considerable fatty infiltration. The pericardium contained about one ounce of serous fluid. The peritoneum contained a considerable quantity of the same kind of fluid. The kidneys were somewhat enlarged and congested. The liver was the ordinary "nutmeg liver." The gall-bladder contained a calculus which filled up the entire fundus. The wall of the bladder was somewhat thickened, and the mucous membrane eroded. There was a cicatrix at the point of contact with the calculus.

Calcareous Deposit in the Pleura.—Dr. Barstow also presented a specimen taken from a man, fifty years of age, who had died of intense acute infectious process, the exact nature of which had not been determined. The plate had been found in two pieces, situated in the right pleural cavity, about opposite the sixth rib. On palpation, before its removal, it had felt not unlike an old fracture of a rib. The two layers of the pleura were everywhere adherent. On section the mass had been found to be composed of calcareous matter, held together by connective tissue. Those masses occurred most commonly after empyema, the fluid portions being absorbed, and the remainder undergoing calcification. The fact that these masses were more commonly found situated at a lower level would suggest the possibility of this one having been formed in connection with an encapsulated empyema.

Dr. James Ewing said that he had quite recently seen a case of empyema that had been operated upon, and in which death had occurred shortly afterward from other causes. At the autopsy a calcareous plate had been found in the pleural cavity, which had reminded him of the specimen just presented. It was about the size of a half-dollar, calcified in the centre, and cartilaginous at its periphery.

Colloid Carcinoma of the Rectum.—Dr. Charles E. Bruce presented for Dr. McAlpin a specimen which had been removed from a woman in St. Vincent's Hospital. She had given a history of chronic constipation and a gradually developing cachexia. The autopsy showed adhesions to the bladder above the rectum, and perforation through the adhesions into the bladder.

A Tubercular Lung.—Dr. Bruce presented a lung removed from a case of tuberculosis. In the right apex was an old cavity surrounded by fibrous tissue. The lung was filled with tubercles and areas of lobar pneumonia. The point of interest was a nodule in the central portion of the lung, the nature of which had not yet been determined, as the autopsy had been made only a few hours before. The report on the

nature of this growth would be presented at some future meeting.

Multiple Abscesses of the Liver and Extensive Tuberculosis.—Dr. Bruce also presented specimens from another case of tuberculosis. The patient, V. L——, twenty-six years of age, a German, had had good health up to April, 1894, at which time a severe diarrhœa developed. He went to the German Hospital, and was discharged "cured" from there on June 6, 1894. While working in a restaurant, and drinking very freely of ice-water during the midsummer, he was seized with severe cramps over the region of the liver, and extending up into the back. The first attack lasted two hours, and after this he usually had one attack in the twenty-four hours. During these attacks he experienced a feeling of swelling and hardness in the right side, and he had a rapid pulse and shortness of breath. When admitted, on August 30, 1894, examination showed the breathing to be very feeble over the lower part of the right lung, with prolonged and high-pitched expiration. The liver dulness was much increased, and there was very great tenderness. There was also severe pain in the lower border of the ribs, one inch inside of the right mammary line. The heart action was regular, but rapid. The lung signs were not prominent. The case at this time had been supposed to be one of hepatic colic. Aspiration of the liver, done at the suggestion of Dr. George P. Biggs, had shown no pus. Numerous tubercle bacilli had been found in the sputum. The man died on January 30, 1895. At the autopsy there was found a marked abdominal ascites. The right lung was compressed and the pleural cavity was filled with fluid. Both lungs showed nodules, cavities, and areas of consolidation. The heart was normal. The spleen was firm and contained tubercular nodules. The liver was very large, and was filled with tubercular nodules, some of which had undergone degeneration and were filled with creamy pus. The intestines were filled with ulcers and small tubercular nodules. The mesenteric glands were enlarged and cheesy. The right kidney contained a large tubercular nodule. There were gall-stones in the common duct. Cultures from the liver pus showed a mixed variety, but no tubercle bacilli.

The President said that, from the repeated attacks of severe diarrhœa with pain in the region of the liver, he had been led to consider the case one of hepatic abscess, and he had therefore suggested aspiration of the liver. Two aspirations had been made, but as they had failed to reveal the presence of pus, he had begun to doubt the correctness of his first diagnosis. The abscesses found in the liver must have been of the ordinary infective kind—at any rate, he had never seen any such tubercular lesion in the liver.

New Mounting Medium.—Dr. Henry S. Stearns presented two slides to illustrate the effect of Dr. Piffard's new mounting medium. These two slides had been taken from the same block of tissue, and stained, washed, dehydrated, and clarified at the same time, and for the same length of time, in each solution. The only difference was that one had been mounted in the ordinary mixture of Canada balsam and xylol, and the other mounted in the new material perfected by Dr. Piffard. It seemed to him that these slides very clearly demonstrated the great value of this new medium. Owing to its very refractive index, minute details of structure could be easily detected with a narrow-angle objective, which could only be discerned with difficulty under a wide-angle objective if the object had been mounted in balsam. This new medium was the ordinary "sweet-gum" of the South, extracted with xylol, and the xylol afterward driven off by heat. Two parts of this sticky gum are to be dissolved in one part of the monobromide of naphthalin, and used exactly in the same way as the ordinary Canada balsam. The ordinary storax had been experimented with, and had given a mounting medium with a refractive index of about one hundred and fifty-eight.

The speaker said that he had found this new medium so superior to the Canada balsam that he did not intend to use the latter hereafter in the college. The section under the microscope was from a glioma of the brain. He had not been able to demonstrate the branching cells in it until he had mounted the specimen in this new medium.

Retro-pharyngeal Abscess.—Dr. George P. Biggs presented specimens from this case. The patient, a child, eighteen months of age, had been a coroner's case in which the diagnosis had been made of diphtheria. At the autopsy, however, nothing had been found except slight parenchymatous change in the organs, until the larynx had been reached. On removing this organ, considerable pus had escaped from the retro-pharyngeal region, and examination then had shown the cavity of a retro-pharyngeal abscess, about three centimetres in diameter. There had been no rupture of the abscess during life. The mucous membrane of the pharynx, tonsils, and larynx was normal, and there was no evidence of diphtheria. Death had been apparently due to the projection forward of the pharyngeal abscess and the consequent occlusion of the rima glottidis.

Perforating Duodenal Ulcer.—Dr. George P. Biggs then presented specimens from a case of perforating duodenal ulcer. The patient, a man thirty-five years of age, had been admitted to the Hudson Street Hospital on April 20th, at 2 P.M., complaining of severe abdominal pain and diarrhœa which had lasted for two or three days. After admission, the bowels were constipated, and he vomited some bloody-looking fluid. The pain was most marked in the lower part of the right side of the abdomen. The abdomen was moderately distended, and there was great tenderness over the whole right side, but especially in the right iliac region. His temperature was 100° F. On the day after admission the abdominal pain was more diffused, and the abdomen was not much swollen, but was quite rigid. The bowels moved freely after an enema. On the next day the pain was less intense, but on the day after this his condition was poor; the abdomen was distended; there was fluid in the right side of the abdomen, and the pulse was rapid, thready, and weak. An exploratory incision was made for the purpose of drainage, as it was supposed that there was an appendicitis and peritonitis. The appendix was found perfectly normal. Five or six ounces of turbid serum were removed from the abdominal cavity, and considerable lymph found over the intestines. The patient died about one hour later. The autopsy showed the small intestine greatly distended and congested, and the peritonitis seemed to be most intense in the pelvis. There were some large hæmorrhoids with superficial ulceration of the mucous membrane. It was at first thought that the inflammation might have extended from here to the peritoneum, but further examination showed this not to be the case. The first portion of the duodenum was adherent to the under-surface of the right lobe of the liver, near the gall-bladder. There were many recent adhesions, and on separating these carefully, a perforation about three millimetres in diameter was found just beyond the pyloric ring, in the base of an old ovoid ulceration. This ulcer was ¾ ctm. in length, and ½ ctm. in diameter, and its long diameter corresponded with the long axis of the intestine. It was in the superior wall of the duodenum. Just enough adhesions had formed around it to prevent the escape of gas. Another old ulceration was found in the posterior wall of the duodenum. The speaker remarked that this had been the third case of perforating duodenal ulcer at that hospital, within a few months, which had been diagnosticated as appendicitis. In all, the symptoms had been localized to the appendix region. All three cases had been operated

upon after there had been unmistakable evidence of peritonitis, but in no instance had there been any relief of the symptoms.

Stated Meeting, May 8, 1895.

GEORGE P. BIGGS, M.D., PRESIDENT, IN THE CHAIR.

A Recurrent Carcinoma of the Breast.—DR. H. J. BOLDT presented several specimens. The first one was obtained from a woman, fifty years of age. The operation had been done by taking away the entire pectoral structures down to the bone. In this instance, he had been obliged to remove a part of the pectoral muscles from the other half of the breast, and dissect out all the glandular structures about the vessels, removing all in one piece. This method of operating would have been adopted at first had it not been that the family had been opposed to such an extensive operation at that time.

Pelvic Abscesses; Vaginal Operation.—The second specimen had been taken from one of a series of thirteen recent cases in which he had resorted to the radical vaginal operation for suppurative disease of the pelvic organs. In this particular case there were five abscesses. The specimen showed a fairly large tumor which had involved the pelvic cavity and had extended half-way up to the umbilicus on the right side. Pus had been removed from below by aspiration and irrigation; then the uterus had been taken out, and the abscess sacs removed piecemeal. The operation was indicated in all those cases of diffuse pelvic suppuration in which the abdominal operations were not appropriate, and in which the pelvic contents were bound down, and there were probably many intestinal adhesions.

Tubal Abortion, with Embryo.—The next specimen was one of tubal abortion, with embryo. The only symptoms of pregnancy that the patient had presented had been that she had not menstruated for ten weeks. There had been no dark discharge from the uterus. The speaker said he had seen her last night in consultation, with the object of determining whether or not she was really pregnant. She had become quite rapidly anæmic in the last few days, but there had been no pain. Examination had shown the uterus to be decidedly enlarged, and a small nodule was situated behind the organ. Bimanual examination had revealed a characteristic crackling feel, indicating to him free fluid in the peritoneal cavity. The uterus had been freely movable. He had made a diagnosis of tubal gestation with rupture. The patient had requested that the operation be postponed until this morning, and on his arrival at the hospital at that time he had found that there had been a fresh hemorrhage and the patient was in a state of collapse. He opened the cul-de-sac of Douglas, and finding the bleeding still active the abdomen was opened. The quantity of blood found in the peritoneal cavity was estimated to be between 2,500 and 3,000 gm. An infusion of saline solution into the cellular tissue was started immediately after the anæsthesia had been begun, and she had received five pints of this solution. She had also received one dose of $\frac{1}{100}$ of a grain of strychnine hypodermatically. It was too early yet to say what would be the outcome of the case.

Ruptured Tubal Pregnancy with Placenta within the Tube.—Dr. Boldt then presented this specimen. It had been taken from a patient, about thirty years of age, who had had children previously. In this case there had been the usual signs of pregnancy, and there had been a progressive intra-peritoneal hemorrhage. He had operated per vaginam, removing the tube, and leaving the clamp in as drainage, in addition to the gauze.

Malignant Deciduoma (?).—The next specimen was from a case of malignant disease complicated with pelvic abscess. The patient being an Italian who was unable to speak English, no history had been obtained. From its general appearance he thought the tumor to be one of malignant deciduoma. If so, it was a rare specimen, and on this account he asked that it be referred to the Committee on Microscopy for examination and report. This was done.

DR. WILLIAM VISSMAN remarked that the locality of this tumor would be very unusual for a carcinoma, and a very probable one for a malignant deciduoma.

DR. BOLDT then presented the following specimens: Cancer in the interior of the cervical canal; cancer of the vaginal portion; two fibromata of the uterus, removed per vaginam; four or five specimens of hysterectomy for chronic inflammatory disease without suppuration, and three dermoid cysts. He said that he felt disposed to strongly advocate the vaginal operation because the patients made a very rapid convalescence, there was no danger of ventral hernia, and the troublesome neuralgic pains sometimes felt in the abdominal scar were avoided. He did not close the peritoneal cavity, and consequently was not afraid of infecting that cavity, the pus draining out from below.

A Method of Preserving the Epithelia of the Gastro-intestinal Tract.—DR. HENRY POWER made a preliminary report on this subject. His idea had been to introduce the preservative into the body, instead of removing portions from the body and placing them in the preservative. His first experiments had been directed toward introducing the preservative into the stomach by puncture, but this method had presented so many difficulties in practice that he had abandoned it. Two rabbits were then killed, and immediately injected by the rectum with Müller's fluid, using 1,500 c.c. of the fluid and a pressure of about four feet. This pressure was continued for twenty-four hours. Examination with the microscope showed that this extreme pressure had injured the tissues, and had caused them to become infiltrated with the fluid. The next experiment was with a two per-cent solution of formalin, and a pressure of from eight to twelve inches, only about one litre of fluid being introduced. This produced very little subcutaneous œdema, and the connective-tissue cells were remarkably well preserved. In another experiment, a dog was killed with chloroform and about one and a half litre of a two per-cent. formalin solution injected into the peritoneal cavity. By this method the large intestine was well preserved. Then a trial was made with a five per-cent. solution of formalin injected into the rectum under a pressure of eight inches, and also with an injection into the peritoneal cavity under a pressure of two feet. In the latter experiment on a large dog the intestine received about two litres and the peritoneal cavity about one litre. After twenty-four hours the tissues were hardened in graduated alcohol, and on microscopical examination it was found that they had been very satisfactorily preserved and without distortion. The method is very simple, and involves practically no marring of the body. Only a minute needle puncture is left in the abdomen. Two rubber douche-bags, a cannula for the rectum, and a large hollow needle for the peritoneal cavity constitute the requisite apparatus. The speaker said that by this method the preservation was more perfect than he had ever seen before.

DR. VISSMAN said that two or three years ago experiments had been made on both the lower animals and on human beings, with a view to determining the best method of irrigating the intestine in cholera. It had been found that the whole gut could be irrigated with a pressure of about four feet. It had not been found necessary in these experiments to tie in the cannula, the use of a large flange answering the same purpose.

Cholethiasis.—The indications for surgical intervention in these cases are to be measured by the danger resulting from frequent attacks of colic and prolonged existence of jaundice.—GERSUNY.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

NOTES ON THE MEETING OF THE BRITISH MEDICAL ASSOCIATION IN LONDON—THE PROCEEDINGS—ENTERTAINMENTS—MUSEUM—PUFFERY, ETC.

London, August 9, 1895.

The British Medical Association has been and gone. The members have returned to their homes or set out on their annual holidays. London has assumed its usual appearance at this season—that is, it is deserted by many of our leaders, who will turn up again late in September, though the dearth of doctors is by no means lamented by those who remain behind.

The meeting was pronounced a successful one, and our guests were generally gratified by their reception. Hospitality was displayed in great variety, and some of the entertainments were exceedingly successful, but London is so vast a place that not a few took the opportunity of examining and enjoying some of its ordinary features, and others who knew it well took some of the more distant excursions. Besides those I have recorded, there was Dr. Down's garden party at Hampton, another at the Children's Hospital, and a third at St. Thomas's Hospital, on the same day, thus dividing the mass of visitors. Then, in the evening a ladies' party in Regent Street Gallery, a reception at Hyde Park, a smoking conversazione at the Clinical Museum, and another by the Masonic Brotherhood at Portman Rooms. The same evening (Thursday), the annual dinner was celebrated in the usual way, when foreign guests were numerous, and complaints about the dinner general. Saturday was the chief excursion day. One party went to Claybury and Epping Forest, and had luncheon as guests of the County Council in their asylum; another were entertained, at Hazlemere, by Mr. Hutchinson; another by Mr. Smith, M.P., at Marlow. Excursions were also arranged to Oxford, Reading, Silchester, Windsor Castle, and Hampton Court. Other contingents went to Hastings and Eastbourne, and it is reported that the last town is desirous that the Association should meet there next year. It would be a popular place. Some places have felt diffident about coming immediately after the great metropolis, and perhaps it would only be fair to select a rather more distant place, and one which would not pretend to vie with the great city, but would give us a a pleasant country outing. But much must depend on the invitations that may be given.

Those of us who accepted Dr. Tuke's invitation (on Wednesday) had a very enjoyable afternoon in the grounds surrounding the beautiful Florentine villa, built by the first Earl of Burlington, and owned now by the Duke of Devonshire. The splendid old cedars of Lebanon forming the avenue, and other beautiful trees, the old-fashioned Italian garden, with its busts and pedestals, and the charming vistas among the trees, make the space of about forty acres perhaps the most beautiful in the neighborhood of London. Nor must I omit the yew hedges of great size and age which one visitor called *yew nique*, and I did not pinch him for his pun! The weather was lovely and the genial hostess and host could not but be gratified with the delight of the brilliant company that had assembled on their invitation.

The Gynecological Society gave a dinner, and the Brussels graduates met to discuss their grievance over the dinner-table. The museum served as a rendezvous, and many pleasant greetings might be there overheard or taken part in. Naturally the venders of all the wares that doctors need were in full force. The manufacturers could not omit so excellent a chance of advertising their productions. The journals, under the guise of reports, give amazing testimonials to these traders. I do not propose to follow the example, but merely say that as a whole the museum was a pleasant lounge, and gave the opportunity of seeing a number of useful articles—both new and old—and comparing them. Further information is to be found in the catalogue and the journal, and will be forwarded by most of the dealers on application. I have always felt an attraction toward the annual museum. I wonder whether it is from a desire to examine and compare the articles on show, or whether it is because the exhibition itself is a sort of microcosm of "this great Association," as the clique continually mouth it. On the one hand, the articles exhibited proclaim their uses and advertise their producers. On the other, the living, breathing, talking members are on show, and together form one gigantic advertisement. And all the year round the official organ of the Association declaims from week to week on the iniquity of puffing, and is itself a standing example of that same wickedness, and its editor about as inconsistent as the medical defender of vaccination, who lowered his flag to the faddists when appealing to them as a candidate.

THE ETHICS OF CRANIOTOMY.

To the Editor of the Medical Record.

Sir: I have been somewhat interested in the discussion, "The Catholic Church and Obstetric Science," which has been going forward in the pages of the Medical Record for some time past. I must say, however, that a good deal of the interest that would otherwise attach to a consideration of the general question of the lawfulness of homicide has been detracted from by the fact that the discussion referred to has been confined merely to whether or not the Catholic Church allows the practice of craniotomy.

To an overwhelming majority of your readers the Catholic Church does not, nor does any church for that matter, speak with authority. I cannot, therefore, think it otherwise than fruitless, not to say irrelevant, that the discussion should be continued within the hitherto narrow limits, especially since such an eminent authority as Father Sabetti has said the last word in behalf of the church.

Human life has always been held in the most sacred estimation among civilized nations, hence the reason for the absorbing interest always manifested by thinking people in all questions relating to the justification of homicide.

True as this observation is, it is no less strange that the members of the medical profession, of all persons the most concerned, and who on occasion are called on to exercise the power of life and death, have always displayed a disposition to shirk the ethics of this subject altogether, or when compelled to notice it, to do so in a lame and hesitating manner.

Truly may it be said that the position of the physician is a strangely unique one, unique in a manner that applies to no other class or calling. No nobler avocation indeed is there than his, and yet none so paradoxical.

On the one hand, it is of the function of his glorious calling to bestow the blessings of health, ay, to restore, in a sense, the very life to poor suffering human beings; while, on the other hand, he is expected, even commanded under pain of reprobation, deliberately to destroy that which it is his greatest privilege and prerogative to save.

The hangman and headsman, it would seem, belong to a rational order of things, for they are but agents of the State, which has legitimate power over life and death. They are free of responsibilty in the premises, and their victims are criminals who justly deserve

death; while the physician combines in himself the offices of judge, jury, and executioner in the case of the innocent and defenceless. Here, indeed, we have the very hyperbole of paradox.

Deprecating as I do the treatment of this question from the point of view of any particular creed, since no creed admittedly speaks with authority to the medical profession, it is with considerable satisfaction that I welcome the article of Dr. William A. Galloway, "Craniotomy and the Law," which appeared in your issue of July 27th.

What commends his article specially to me is that it aims to treat this grave question in a secular, as distinguished from a sectarian, manner. There ought, therefore, to be no place for the introduction of such digressing issues as the odium *anti-theologicum*, or of special pleading, in the interest of any particular religious system.

Dr. Galloway bases his argument for the lawfulness of craniotomy in the teachings of common law, contending, at least implicitly, that it is unnecessary to seek farther the desired justification. However, the basis of common law, though broad, is certainly not broad enough for the consideration of such a question as the present one. His coolness rises to sublime heights, in thus assuming infallibility for common law, ignoring the very important fact that behind it there is another and higher law, whose imperative, to everyone with a conscience, is ultimate. It evidently never occurs to him that some time could be profitably spent in research, with the view to discovering how often common-law maxims seen to be at variance with the principles of morality, have been abrogated by statutory enactment.

Now, the maxims of common law relating to craniotomy, the statutes in conformity therewith, as well as Dr. Galloway's arguments (some of them at least), rest on a basis of pure unmitigated expediency, and this is certainly in direct contravention of the teachings of all schools of moral science, even the utilitarian.

To show this, I quote some passages from his article: "It" (the Ohio statute) "provides that craniotomy may be done to save the life of the mother; hence when the question is between an unborn infant's life and that of the mother, the mother's is to be preferred." Why the mother's is to be preferred, he tells us further on, where he says: "The duty he" (the physician) "owes to society at large in saving the *mature* and *useful* life of the mother as against the life of the child, which in its *useful* relations to the social body is yet *immature*" (the italics are mine), "is above and beyond adverse legislation."

In order to strengthen his position by showing that the case of the fœtus in utero, in this emergency, does not stand alone, but is one among many in the different contingencies of life, he introduces what he thinks is an analogous case. He says: "Upon the authority of Lord Bacon it has always been held in law and fact, when two shipwrecked persons get on the same plank, and one of them finding it unable to save them, thrusts the other from it, whereby he is drowned, it is justifiable homicide." That the governing principle here is not utility, and that the analogy is a false one, will be shown further on.

But why, some may ask, is not utility a sufficient justification? That it is not only not sufficient, but in no sense a justification at all, can best be shown by stating a case of mother and fœtus, essentially like the above, but with the normal attribute of the two reversed. Let us suppose the case of a mother who, instead of a blessing, has been a scourge to society, and that an individual, it might be the father, and he a great and good ruler without an heir, stands pledged to insure the future usefulness of the child to society. Will any one outside a lunatic asylum justify in this case the deliberate and direct killing of the mother to save the child? And yet if utility be a just reason, why should it not be done? Why should the mother receive any consideration whatever?

With regard to the precept against taking human life in its general meaning, there is no difference of opinion between Dr. Galloway and myself.

What I object to, however, is that the tone of his language in describing the exceptions to it bears the implication that not to moral, but to human, law are to be traced the ultimate sanctions for conduct in the circumstances under consideration. The exceptions he cites are reasonable and just, and in strict accord with sound morality. He gives five of these, four of which in their last analysis are reducible to one—self-defence. The fourth, which he calls superior duty, is not relevant here and need not therefore be considered.

Here Dr. Galloway, in addition to utility, puts forward self-defence as a justification, and in this I am at one with him. He falls into grave error, however, in his application of this principle when he considers the fœtus the aggressor. That the mother and not the fœtus is the aggressor, I think can be plainly shown.

Let us see. The child's presence in utero is due to no act of its own, but to the conscious and deliberate act of the father and mother. Again, the assault begins, continues, and ends in the tissues of the mother. There is no controverting the fact that the acts of the mother, from the first of copulation, which is voluntary, to the last of parturition, which is consequentially so, are positive and active, while those of the child are merely passive. This being so, how, by any distortion of thought or language, can the child be considered in that condition of activity connoted by the word aggressor? The fœtus has a right to its life as against the mother, not on any mere grounds of shifting expediency, but according to right, reason, and morals, and deliberately and directly to deprive it of that life is an unjustifiable act in no way distinguishable from a like act in the case of an adult and called by a name that "hath not a pleasant sound i' the ear."

At this point I will make good the assertion that the analogy between the obstetric case and that of the shipwrecked persons is a false one. Before doing so, however, I will state that even if the analogy were true it is by no means on the principle of utility that he who kills the other is warranted in doing so. His right is based on the law older than the churches and than all human enactments, yes, even older than Moses and the Decalogue, that is, the law of self-preservation. For it is evident that if utility is here the determining element the same practice should hold as in the obstetric case.

Suppose, for instance, that of the two persons on the plank, one was known to be a highly useful member of society and the other a degraded criminal, why should not the latter be held culpable if he succeed in killing the former? It is only necessary to state the case to lay bare its absurdity.

The attempt to establish an analogy between this case and the obstetric one is unfortunate in this, that in the latter there is an unjust aggressor—the mother—while in the former there exists the strange but nevertheless real condition of two persons, each of whom is both an aggressor (though not an unjust one) and an aggressed, and justification is with him that succeeds.

I stated above that even the utilitarian school of moral science would not justify the taking of human life for merely expedient reasons, and this assertion perhaps needs some explanation and amplification. According to this school utility is only made use of to furnish reasonable sanctions for ultimate moral laws, and is in no way to be applied in particular and concrete cases. The case of the shipwrecked illustrates this most admirably. The teachings of this school would never countenance the rule that the less must give way to more worthy. If, on the other hand, he turn to that other great school of ethics, known as the traditional or intentive, the advocate of craniotomy will find less consolation and encouragement.

Thus I affirm, it is plainly seen that there is no system of moral science whose teachings can be appealed to in support of Dr. Galloway's contentions. There is nothing, then, for him to do but either to accept the behests of the moral law as we now understand them or to found a new school. To do this latter, however, he must discover some principle or principles of ethics that have hitherto eluded the profound thinkers of the past, for most surely the principles he advances, if pushed to their legitimate logical consequences, will lead to moral chaos.

THOMAS J. KEARNEY, M.D.

NEW YORK, August 6, 1895.

BLOOD CHANGES IN NEURASTHENIA.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: In the issue of July 27th you refer disparagingly to my remarks, made several months ago before the St. Louis Medical Society, about certain blood changes which I discovered in typical cases of neurasthenia. You have no very exalted opinion of blood examinations in general, and consider them unreliable. Permit me to say, that I fully concur with you so far as the distrust of new discoveries or alleged discoveries about the physiology and anatomy of the blood is concerned. There is no field in the medical sciences that is less cultivated than hæmatology. The superstitions which have from time immemorial supplanted exact knowledge about the morphologic constituents of the blood, still flourish with unabated vigor. The anomalous appearances of the red blood-corpuscles and their deviation from the typical cells, the want of information about the character and prevenience of the uncolored corpuscular elements of the blood—all these defects of our knowledge, and many more, too numerous to mention—have given rise to a flood of hypotheses and fantastic theories, which, by the majority of the medical profession, are believed as if they were proven facts. Thus the prevailing teachings concerning coagulation and thrombus-formation are predicated at all the medical schools as solid facts. In reality they are fundamentally erroneous, as I shall try to demonstrate in a future publication. On this occasion I shall also show what undreamt of morphologic characters of the blood-elements may be brought out by improved staining methods. Permit me to cite as one of the results of these methods, already published by me, the infallible anilin color-reaction of diabetic blood. By this method it is possible to pick out a diabetic with absolute certainty from any number of healthy persons, or such as suffer from diseases other than diabetes or glycosuria.

An extensive article entitled "On the Blood Changes in Neurasthenia, together with some remarks on the Anatomy of the Blood," will soon appear in the *American Journal of the Medical Sciences*. I think that the illustrations accompanying this article will throw some light on a hitherto unexplored and dark subject.

Finally, permit me to state that I consider the belief which, with most medical men, amounts almost to an axiom, that the bromides act as destroyers of the red blood-corpuscles, is one of the superstitions previously referred to. The deleterious action of these drugs on the blood has never been demonstrated by experiment. That excessive or long-continued dosing with bromides will produce cachexia and anæmia (so-called) is a well-known fact. But this is also true of other drugs, when continued too long or administered in excessive doses. Thus, phosphorus, arsenic, and even iron will have this effect if improperly given. Besides, I have not said that the bromides were *the* remedy for neurasthenia; in the course of my cursory remarks before the Society I only incidentally mentioned the fact that the platelets, which previously to the administration of sleep- and rest-producing doses of bromides had been very numerous, were reduced in number to physiologic quantities. I consider the bromides as *one* of the remedies in *some* of the cases of neurasthenia. This can be proven by the examination of the blood made before and after the administration of the drug. I positively know, that the platelets in these cases diminish in numbers, *i.e.*, that the excessive decay of the red blood-corpuscles is arrested.

Respectfully,
LUDWIG BREMER, M.D.

ST. LOUIS, MO.

STERILIZED MILK AND FREE LUNCH.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: This is the microbian era, in which most of our fleshly ills are causatively referred to specific bacteria, and consequently our faculties are more than ever observant of septic possibilities, not only within the clinical domain, but also in the ordinary careless habits of humanity. The presence of two physicians as public and unthinking participators in the unsanitary practices of the rabble, is the inspiring motive for the succeeding remarks. One of our guild held his position one sweltering day, in a line of drinkers leading to a sterilized milk station, and the other doctor regaled himself at the free-lunch counter of a public house.

The disgusting certainties imparted to this brand of milk by reason of slovenly handling in the outfits generously provided by Mr. Strauss, of New York City, will claim the first word, after which will be noted the potency for evil presiding over the free-lunch board, so temptingly displayed to the patron of the saloon.

With the philanthropic intention of lessening the death-rate among the children of the poor, due to the use of polluted milk, and with the further purpose of furnishing a healthy thirst assuager to the public, Mr. Strauss is maintaining booths or depots for the distribution of sterilized milk, at or below cost, to all comers. While there is no denying the good thereby done to the metropolitan infants when the sterilized article is conveyed home in clean, closed vessels, there is, on the other hand, not a particle of extra safety in the identical commodity sold by the glass at the same stations.

People of every condition apply at these depots, from well-attired, cleanly folk, down through every degree of descent to unwashed vagrants, all enjoyably disposing of the supposed hygienic beverage, while the fastidious spectator dubiously observes the untidy method of dispensing. As each customer drinks his allowance, the attendant receives the emptied drinking-vessel, dips it into a tub of water, agitates it therein a few times, and places it upon the shelf to drain, there to await the salute of after-coming lips. The first glass of milk might be regarded as sterile, but such a claim could not be conceded to those following. Each succeeding glass that is immersed in the rinsing fluid, adds its portion of milk dregs together with whatever contamination has been bequeathed by the hand and mouth of the consumer. It requires but a momentary consideration to demonstrate upon what a frail reed of safety those thirsty throngs rely as they eagerly jostle for the coveted draught, befouled with vileness from the unbrushed teeth of the negligent, the filthy mustache of the rhinitic, and the lip of the syphilitic. The refined nature of a cleanly person revolts at the menu of human dirtiness thus partaken by an uncritical contingent of his fellows, beguiled into a sense of comfortable security by the claim of sterility, a pretension that would be fairly incontestable if running-water cleansing were provided.

To those whose tastes seek gratification in the saloon, there is an equally great risk resident in the gratuitous provender awaiting the attention of every visitor. The alluring picture of snowy table-cloth, gleaming glass-

ware, rich china, and varied viands, which assails the senses and magnetically draws its ever-present group of nibblers, is, despite its charming setting, a veritable "whited sepulchre." Cheese of every age, tint, odor, and grade of viability handled by every guest; pickled oysters speared with a fork that finds its way into the mouth of every user, or, often more primitively fished out by unspeakable fingers; dishes of salt into which the pungent radish is dipped between the bites that precede its final mastication; platters of meat wherein the slices are sorted over by the uncertain hands of *bon vivants;* salads in every variety of conglomeration, appropriated in all the conceivable methods naturally befitting the breeding of the luncher; the dangling towel bearing the imprint of soiled fingers, and serving as a universal napkin; and every other ingredient of the publican's bill of fare receives its quota of infection from the touch of unkempt, tipsy, and diseased patrons. Culture have been made from material derived from the sterilized milk depot and the free-lunch counter, and an inspection of the abounding malignant organisms thus generated would considerably surprise the uninitiated, as he recognized the familiar bacteria of the graver forms of disease.

In office, workshop, bedside, public conveyance, and in every attitude of life, all are exposed in manifold ways, and the danger, though appreciated or not, is in the nature of things unavoidable, unless we isolate ourselves from social, business, and charitable relationship with mankind. In the case of those ills which might be escaped, the physician should ever remember that "example is better than precept" in the estimation of the world, which is not slow to discern a disregard for professional proprieties.

SAMUEL J. JOHNSON, M.D.

MOUNT VERNON, N. Y.

A SHORTER SCALE FOR THE THERMOMETER.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: Much thought and scheming has been expended upon the method of arranging thermometers in cases for the convenience of carrying and handling, and the avoidance of loss and breakage. Various changes, also, have been made in the shape of the column to lessen the difficulty of rapidly reading the scale; an opaque background has been put to a clear cylinder, and possibly the most noticeable improvement is the magnifying thermometer.

But why is the thermometer encumbered by so large a range of degrees? The thermometer now in my possession, purchased recently and one of the standard makes, is marked from 95° to 115° F. Some of the thermometers register only to 110° F.; the latter gives a range of 15°, and the former 20° F. Is the downward reading to 95° F. ever needed? and how very rarely has a physician occasion to use the scale above 107° F. It is likely that the majority of general practitioners never are brought to the trying ordeal of watching or combating a temperature rising above 107° F.

Supposing this to be the case, start the scale at 98° F., and stop at 107° F., and there are only nine degrees to be recorded on the thermometer, commencing at nearly a degree below normal, and including the point of high degree, rarely exceeded. Such a scale, then, would satisfy the demands of all ordinary cases of the busy practitioner; would permit of the degree spaces being much larger than now made; would materially simplify the reading of the temperature, which needs often to be done hurriedly, and in the sick-room, where the light is insufficient for easily seeing the small markings; and would especially allow of the divisions of the degrees to be made more distinct and thereby facilitate the correct reading of the fractional parts of the degrees, and afford the opportunity of a far more accurate record of the variations of the temperature.

Further, if the scale included only 9° F., and the degree spaces were of the same size as now ordinarily made, it would permit of a shorter thermometer that might be desirable to many. It might be short enough to be worn as a charm on a watch chain, or carried in the vest pocket as a penknife.

The thermometer, with the degrees thus limited and enlarged, would serve the doctor or the nurse in almost all cases, and with an easier reading. If deemed necessary, a thermometer indicating from 95° to 110° F., could be kept for the rare cases requiring such a range.

A leading manufacturer informs me that such a thermometer, with the degree spaces of any size desired, can be made with accuracy, and be much more easily read, as well as give more definiteness to the fractional parts of the degrees.

ELMAR C. FAHRNEY, M.D.

HARRISBURG, PA.

THE CAUSE OF FLATULENCE.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: In the MEDICAL RECORD of August 10th, considerable editorial space is devoted to an article on Flatulence, by Dr. Stephen McKenzie. It is stated that the gist of Dr. McKenzie's paper, as regards the etiology of flatulence, is, that "the walls of the stomach being weak and flabby and lacking in tone, suddenly dilate, and the volume of gas, which was before somewhat compressed, expands and fills out the enlarged viscus. Dr. McKenzie states that the gas does not increase in quantity in the stomach, but only in volume."

The above statement seems to be incompatible with certain well-known physical laws, as well as with known vital principles:

First, his theory supposes a certain considerable amount of gas constantly present in the stomach; granting this, what must be the condition of this gas as regards its elastic tension? Either the gas must be compressed during all the period of time when flatulence is absent, and this compression must be maintained by a tonic contraction of the stomach walls, or else the gas must be subject to the normal or existing atmospheric pressure, in which latter event relaxation of the muscular walls could not affect its volume. To make our meaning plain, suppose a rubber bag of a capacity of one gallon, have two quarts of gas put into it and then be closed; the bag would be perfectly relaxed, and yet the volume of gas would remain two quarts unless the temperature were changed or the outside pressure altered. If the bag were placed under the receiver of an air-pump and the air exhausted, then the elastic tension of the enclosed gas would come into play and the bag might be filled or distended. Now, what must be the conditions surrounding the stomach? must not its walls be constantly subject to the surrounding atmospheric pressure from without? Suppose there be a change in the contents of the abdominal cavity, would not this be instantly compensated for by the atmospheric pressure from without? Can we conceive of a partial vacuum in the cavity when it is enclosed by soft parts in contact with the air? or can we conceive of a gaseous distention of the stomach, except the gas be generated within and finding no escape, distends the organ, and with it also the abdominal walls?

Under the assumption of Dr. McKenzie, the volume of gas constantly in the stomach must, as we have shown, be materially compressed, otherwise it could not expand. This compression must be maintained by the active contraction of the stomach walls. Is it conceivable that a weak and flabby stomach could resist any material pressure for hours at a time? is not such an assumption at variance with all known laws of muscu-

lar contractility, and must not Dr. McKenzie seek for some other explanation than an expansion of volume? Would it not be more rational to assume that a weak and dilated stomach, being unable to completely expel its contents, has constantly in it a residuum of fermentative material, twenty-four to forty-eight hours old if need be, and which, under favorable conditions, suddenly splits up, evolving rapidly large amounts of gas?

LOUIS H. JONES, M.D.,
Professor of Chemistry, Atlanta Medical College.

New Instruments.

AN EASY AND READY METHOD OF CIRCUMCISION.

BY JOHN W. ROSS, SURGEON, U. S. NAVY (RETIRED),
PROFESSOR OF OBSTETRICS AND CLINICAL SURGERY, SEWANEE MEDICAL COLLEGE.

RETRACT the foreskin; insert the glans penis up to the corona into the open mouth of a glass tube; draw the foreskin well forward over the end of the tube; tie a strong, small silk cord very tightly around the foreskin immediately in front of the flange of the tube; amputate the foreskin one-eighth of an inch in front of the constricting cord by a circular sweep of the knife; unite the mucous and cutaneous edges of the stump of the prepuce by eight or ten fine interrupted sutures; cut the constricting cord; remove the tube; cover the cut edges well with powdered iodoform; encircle the anterior half of the penis with a roller bandage of iodoform gauze, allowing the meatus to project slightly for facility of urination without soiling or removal of the dressing; and keep the patient in bed, with the penis elevated, for from twenty-four to forty-eight hours.

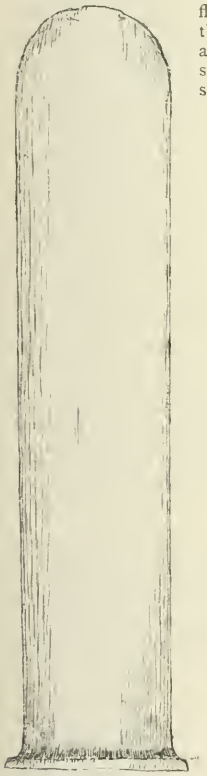

FIG. 1.—Showing a Largish, Strong Test-tube with which several adult circumcisions have been done.

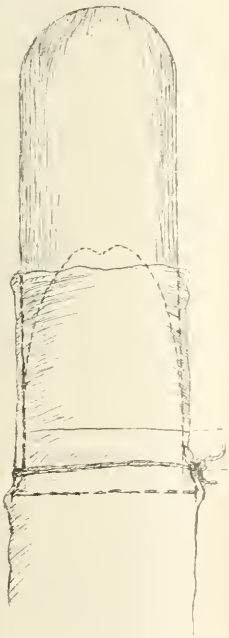

FIG. 2.—Showing Semi-diagrammatically the Tube *in situ* between the Superincent Prepuce and the Subjacent Glans Penis, and demonstrating the more Distinctive Features of the Operation.

In cases of phimosis the prepuce should be divided dorsally sufficiently to allow its easy retraction over the corona. The fact that the longitudinal cut edges will not coapt along the tube is of little or no importance. The slit foreskin should be spread around the tube as accurately as practicable, and the operation proceeded with as usual. If deemed advisable, the little notch in the prepuce just above the cord may be closed with a suture or two, involving only the integument.

I have generally used test-tubes, as they are almost invariably at hand, of sizes suitable for infants or adults. But pretty much anything of the kind will do, such as urinometer-tubes, slender, large-mouthed bottles (neckless ones preferably), which are to be found in all drug-stores. For adults, the tube should be strong enough not to be easily crushed, and its mouth should be surmounted by a rather abrupt rim, free from cutting edges. Should the flange not be high enough, or rounded enough, it may easily be made so by winding a strong wax thread tightly around and around, behind and against it. I have made an excellent apparatus by thus wrapping with a thread the open end of a flangeless urinometer-tube until a suitable ridge was built up. The lumen should correspond with the diameter of the glans about one-eighth of an inch anterior to the corona. It has been found better not to remove more of the foreskin than can be with moderate force drawn in front of the flange at that point.

The constricting cord should be about the size of the ordinary silver probe of the pocket cases. In adults it should be drawn very tightly indeed around the prepuce, compressing this strongly against the tube. I draw it almost as tightly as I can with the fingers, and have never known it to do the slightest harm to the tissues. When this has been done, I have never known the skin to slip from under the cord, and have never been troubled with hemorrhage, either during or after the operation.

It is generally better to give ether to children, and to inject cocaine in front of the constricting cord in adults. The advantages of this method are its bloodlessness, its simplicity of technique, and the fact that no special instrument or apparatus is required, everything necessary for its performance upon the largest or smallest penis being found in the physician's house or in the average drug-store.

The above-described method of circumcision is virtually the same in principle as that detailed by me in the MEDICAL RECORD of September 26, 1885, a ring of hard rubber being used in that operation instead of the tube. It proved difficult to keep the ring in position under the foreskin. The tube, however, projecting as it does beyond the foreskin, is under complete control.

The earlier operation and "Ross's Circumcision Ring" are described and figured in the second edition of Stephen Smith's "Operative Surgery," page 712.

Intestinal Anastomosis.—There are three chief points to be considered in effecting an astomosis, or in suturing a wound of intestine: 1. That adequately broad and sufficiently wide surfaces of healthy intestine should be in contact. 2. That though it is advisable to exclude the mucous membrane from the stitches, the fibres of the submucous coat must always be included. 3. That the operation should be performed as rapidly as possible.—BIDWELL.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending August 24, 1895.

	Cases.	Deaths.
Tuberculosis	161	118
Typhoid fever	28	14
Scarlet fever	28	4
Cerebro-spinal meningitis	0	2
Measles	123	16
Diphtheria	127	27

Duplex Personality.—Dr. R. Osgood Mason, in a recent paper on "Duplex Personality. Its Relations to Hypnotism and also to Lucidity," makes the following points: First, that there are now on record many well-authenticated cases where, from a condition of syncope brought about by pain, weakness, or long-continued illness, from epileptiform attacks, loss of consciousness from shock or other physical causes, patients have emerged into an entirely new and unusual condition. In this new condition the individual thinks, speaks, and acts in a manner entirely different from the usual or primary personality. Even physical conditions are changed. In one case, from a condition of wretched bodily health accompanied by epileptiform attacks, indolence, and melancholia, the patient emerged into a state of excellent health accompanied by industry and cheerfulness, and without a trace of epilepsy, hysteria, or melancholia; in fact it was an entirely new and different consciousness and personality. During this second condition the primary consciousness is entirely blotted out, and the time so occupied is a blank. The second consciousness or personality, on the other hand, knows of the primary self, but only as another and distinct person, having no special relations to itself, and with whom it does not wish to be confounded. It has opinions, sentiments, memories, a personal history, in fact a character altogether independent and often entirely different from the primary self, but sane, consistent with itself, and in harmony with its surroundings. This second personality may continue for a few minutes or hours, and may alternate frequently with the primary self, or it may remain months and even years at a time, and so become the dominant personality, alternating only seldom with the primary self. In either case all the occasions when this second self is present are linked together in one distinct chain of memories, forming a personality just as consciously distinct as the primary self. On close examination and comparison it is found that this second personality presents very marked analogies to the condition of somnambulism in ordinary sleep. Again, it is found to be identical with the condition of somnambulism which occurs in the hypnotic state, and in some instances, as that of Ansel Bourn, the second personality has repeatedly been brought into activity by hypnotism.

Here, then, are three distinct conditions in which a second consciousness or personality is brought to the surface and becomes the ruling personality to the exclusion of the primary self, namely, loss of consciousness from disease, shock, or other physical causes, ordinary sleep, and the hypnotic trance. Examining closely the personalities apparent in these conditions, and especially in the condition of ordinary somnambulism and that of the hypnotic trance, we find certain supra-normal faculties present in these new or second personalities not present in the normal or primary personality, especially the faculty of supra-normal vision. This alleged fact is not generally accepted, because from the stand-point of the ordinary laws of optics acting upon physical organs, such vision is of course impossible. But within the past ten years the subject has been systematically studied as never before, and the evidence of such vision is simply overwhelming. But it is the subliminal self, and not the primary self, which possesses this power. This supra-normal vision is also sometimes exercised in dreams and in reverie.

The following conclusions are drawn: 1. That there does exist in some persons, probably in all, a subliminal self or second personality, whose action is not strictly limited by the physical body, and which possesses perceptive powers far exceeding those of the primary self. 2. That lucidity or clairvoyance is an attribute of the subliminal self, and in that view is perfectly reasonable and is a proper subject of investigation by scientific methods. 3. That hypnotism is a means of experimentally bringing this subliminal self with its added perceptive powers into action.

Intestinal Resection.—The cicatrix does not contract. In intestinal obstruction, resection with end-to-end union gives better results than lateral approximation, and should always be performed when practicable. The same operation should always be done in gangrenous hernia. In fecal fistula the bowel should be resected and united end to end. Patients should receive liquid nourishment as soon as the effect of the anæsthetic passes off. The bowels should be made to move as soon as possible after the operation, and frequent evacuations kept up. If the button does not pass in three or four weeks, the rectum should be examined, as it may rest just inside the sphincter. There has been one case reported of occlusion of the button by fecal impaction in the cylinder. This can be easily avoided by cathartics immediately after the operation. When returning to the abdomen, the intestines should be placed in parallel lines, especially at the seat of approximation, to prevent sharp curves and obstructions. There is no danger of obstruction from the button, as not a single case has been reported. There is no danger of extension of pressure atrophy beyond the line of pressure. Primary adhesions may be hastened in malignant cases by abrading the peritoneum with a needle. In ordinary cases this is unnecessary. A supporting suture is never necessary to secure union, and should only be used to relieve tension when the viscera approximated are forced out of position. The mucous membrane should be pushed down in the cup of the button before closing it; if redundant, it should be trimmed off with scissors. It should never be allowed to protrude between the edges of the button when the button is closed.—Murphy.

Lacerated Cervix.—1. That suturing the lacerated cervix properly, immediately after the labor, will result in primary union of the same and prevent many of the evils that follow in the wake of a union by second intention. 2. That the fear of septicæmia attending the manipulation of the cervix, and the introduction of poisons, which will induce septicæmia at the same time, is an unfounded one, and would be dissipated by giving such work a proper test. 3. That it is a method of procedure more justifiable than an immediate repair of the perineum, which the profession of to-day universally advocates. 4. That the securing of primary restoration of the laceration hastens involution, prevents subinvolution, and the various forms of displacement which are induced by it in such an overweighted organ. 5. That catgut is the proper suture, and perfectly safe and reliable when carefully prepared.—Dudley.

Hypertrophied Tonsil.—The action of the tensor and levator palati muscles, which largely control the air supply of the middle ear, is interfered with by the pressure of hypertrophied tonsils, thus causing impairment of hearing.

PRACTICAL URETHROSCOPY.

BY H. R. WOSSIDLO, M.D.,

BERLIN, GERMANY.

THE diagnosis of urethral diseases, strangely enough, still maintains a peculiar and distinct position in medical science. While in all the other specialties inspection of the organs is carried as far as possible, there are even now genito-urinary specialists who consider urethroscopy unnecessary. Those who do not confess it openly prove it by not using the urethroscope.

Would it not be most grave dereliction to neglect the laryngoscope in a throat affection, or to attempt to treat an aural disease without the otoscope?

It is an equally self-evident proposition that we cannot diagnose urethral affections without ocular exploration. Naturally this is inhibited in acute urethritis, for the irritation which the endoscope would then produce would violate one of the most fundamental surgical principles.

The diagnosis of chronic gonorrhœa is generally based upon the following symptoms: Occasional or constant appearance of a small quantity of mucopurulent or mucous discharge, especially in the morning; filaments in the urine, and principally on the presence of gonococci in the secretion or in the filaments.

Microscopical examination of the discharge for gonococci, leucocytes, etc., is, beyond cavil, an effective means of diagnosis, and is requisite in every case of chronic gonorrhœa. The discovery of gonococci in the discharge or in the filaments is conclusive for the existence of gonorrhœa and for its infectious nature. But it is generally acknowledged that the presence of gonococci in the secretion is not constant. The filaments or the discharge may be examined for weeks or months without finding gonococci. If the patient be then dismissed as cured, a most painful surprise may follow by a gynecologist finding gonorrhœal infection of the patient's wife, who had been in perfect health until her husband was permitted to resume sexual relations with her.

The appearance of filaments in the urine warrants the conclusion that desquamation and inflammatory exudation is still taking place; but their presence does not prove that the discharge is still infectious. Neisser, of Breslau, to confirm the diagnosis, recommended artificial irritation of the urethra by injecting a solution of nitrate of silver. Very often gonococci will again be found in the muco-purulent secretion reawakened by these injections. But in many instances no gonococci will be found, despite frequently repeated irritating injections. And even then the patient may not be cured.

Men oftentimes will consult physicians on the propriety of marriage. Such a case may have had gonorrhœa some years before, and wishes to know if he may consider himself perfectly cured. On examination neither secretion nor filaments nor gonococci may be found, and still the man may not be cured, as is shown by a case narrated by Oberlaender, of Dresden.[1]

[1] Ueber die praktische Bedeutung des Gonococcus, von Dr. F. M. Oberlaender. Berliner Klinik, 1888, Heft 5.

A physician, who had his last attack of gonorrhœa six years previously, called on Oberlaender on account of a bladder weakness. He had recovered quickly and apparently entirely from his previous gonorrhœa. He had had no discharge or any other symptoms for five years. About four years before he had an attack of rheumatism, followed by almost annual recurrences. He was married about three years ago. His wife aborted in the fifth month of pregnancy; this was followed by gonorrhœal endometritis. Then the patient began to experience vesical weakness. The urethroscope revealed indisputable chronic urethritis. Appropriate treatment caused the urethritis to subside; the rheumatic attacks ceased and the bladder symptoms disappeared.

I may add here a case of my own. One of my patients consulted me not long ago regarding a peculiar twisting of the urinal stream, which he attributed to a possible stricture. Nine years before he had gonorrhœa, of which he considered himself perfectly cured, as he never had any symptoms thereof since. At the time of the consultation the possibility of a fresh infection was out of question.

Superficial examination showed no discharge, few filaments only, no gonococci; a large-sized sound passed the urethra easily. The urethroscope showed some infiltration of the urethra and several diseased glands. I succeeded in removing a little secretion from one of these glands. To our great surprise it revealed gonococci.

Such cases will occasionally occur. In view of such facts alone, even entirely by themselves, ay, without resorting to analogies of any kind, must a specialist, and especially the urologist, not be required to employ all available diagnostic means? What would be thought of a physician if he limited his examination of a case of tuberculosis to what bacteriology of the sputum revealed, without inquiring into the pathological changes of the lungs by percussion and auscultation?

If we further remember the fearful havoc gonorrhœa exerts in women as well as in men, can it be permissible to neglect even one means of confirming the diagnosis? These points alone demonstrate beyond all and any peradventure that urethroscopy is necessary for the diagnosis of chronic gonorrhœa. It is most sadly surprising that this proposition is not universally accepted, at least not in deed.

The disregard for urethroscopy may be due to defective methods for illuminating the urethral canal which have been used until now. A brief historical sketch will illustrate this:

The first attempt to inspect the urethral canal was made by Bozzini, of Frankfort, at the beginning of this century. He constructed an apparatus for examination of the "canals and cavities of the human body," a part of which was designed for urethral inspection. His invention fell into oblivion, and nothing further is recorded of attempts at urethroscopy until Segalas, in 1826, constructed a new instrument, which he called "speculum urethro-cystique." About the same time a similar apparatus was invented by an American, John Fisher, and, 1840, by an English physician, Avery. Ratier (1843) and Cazenave (1848) constructed diaphanoscopic instruments.

None of these instruments, however, came into general use, and even were soon forgotten. It was left to

Désormeaux to raise endoscopy to a scientific basis, so that he may justly be called the father of endoscopy. In 1853 he demonstrated his instrument at the Académie de Médecine de Paris; in 1865 he published his work "De l'Endoscope et ses applications au diagnostic et au traitement des affections de l'urèthre et de la vessie." Désormeaux's instrument was modified by Fürstenheim, Tarnowsky, and others. All these endoscopes proved too complicated and cumbersome, the urethral tube and the lamp being affixed in one piece. The necessity was felt to separate the light from the tube and to throw the light into the urethral canal by means of a reflector.

Grünfeld, of Vienna, was the first to make endoscopy popular with the medical profession. His book on endoscopy of the urethra and bladder is the first standard work published on this subject. He first used a petroleum lamp as the source of his light, which he threw into the urethra with the usual laryngoscopical reflector. He devised several endoscopic tubes, of various lengths, some of them open, others fenestrated in front or at the end.

Grünfeld's simple instrument underwent several modifications, of which that of Klotz, of New York, merits special mention.

The introduction of electric light for diagnostic purposes into medical practice gave birth to a number of new inventions. At present most specialists use the electric light for examining the urethra.

We may divide the various endoscopes now in use into two classes: 1, Those which throw electric light into the urethra by means of reflectors or prisms; and 2, those which directly illuminate the urethra by directly putting the light into it. Of the former, Leiter's, Lang's, Otis's, Casper's, and Antal's urethroscopes are the best known. These electro-endoscopes consist of a short tube to whose ocular end the illuminating apparatus is attached. The latter is a mignon-lamp, whose light is reflected by a mirror or prism into the urethral canal.

Direct illumination of the urethra was invented by Nitze, in 1877. It was left to Oberlaender, of Dresden, aided by this urethroscope, to teach the differentiation of anatomical changes in chronic gonorrhœa, and to make a new departure in its treatment.

Besides several articles, he published in 1888 his book, "Beiträge zur Pathologie und Therapie des chronischen Trippers," and in 1893 his "Lehrbuch der Urethroskopie," which is a standard work on this subject.

At present the value of the two methods is the subject of a controversy which has been made needlessly acrimonious, based perhaps principally upon the value of each instrument in its inventor's hands. But the conviction must remain that from discussion, however conducted, truth must eventually prevail. This is neither the time nor the place to enter into the merits of the dispute. A few simple facts, however, will be mentioned in connection with the instrument I use and intend to describe in these pages. It is the Nitze-Oberlaender urethroscope.

The endoscopic tubes are made of silver, which produces the least disturbing reflexes, is most durable and useful. The tubes we use have a calibre of 23, 25, 27, 29, 31 Fil. Charrière. Oberlaender, and Kollmann, of Leipzig, have shown the advisability of employing large-sized urethral tubes. Their use quickly convinces one that they rest quite loosely in the urethra.

The only difficulty in introducing large tubes may be experienced at the external orifice or at the valve of

FIG. 1.—The Original Nitze Urethroscope.

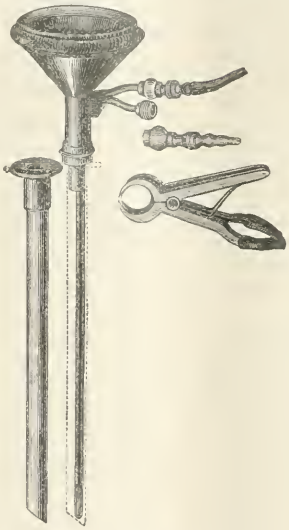

FIG. 2.—The Nitze Leiter Urethroscope.

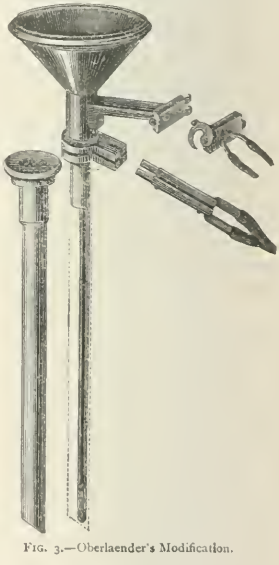

FIG. 3.—Oberlaender's Modification.

Guérin, which, when present, is situated at the end of the fossa navicularis. In the cavernous portion and at the bulb the urethral canal is naturally wide, and can in relatively many cases easily be passed by tubes of calibre 31 Charrière. The lining membrane of the urethra being longitudinally folded, it is desirable that these folds be smoothed out during examination. And

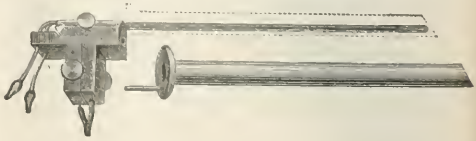

FIG. 4.—The Nitze-Oberlaender Urethroscope, modified by C. G. Heynemann.

this requires large-sized tubes. The extra-urethral rim of the tube has a spur to which the light-carrier can be affixed.

The light-carrier consists of two wires which conduct the electric current to platinum wire, the one being insulated, the other not. They rest upon a tunnelled bar, through which cold water circulates. The slender and

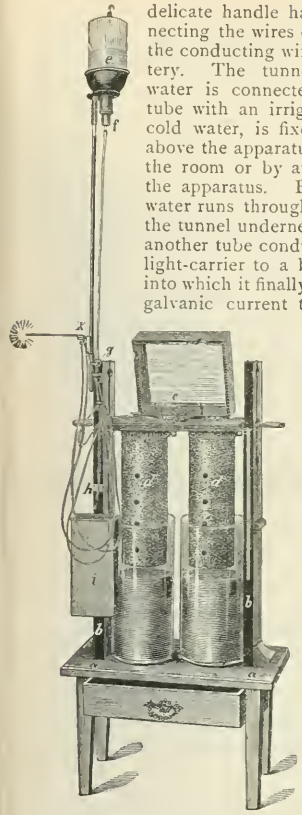

Fig. 5.—Oberlaender's Electro-urethroscopic Apparatus, Chromic Acid Battery, Cooling Device, and Urethroscope.

delicate handle has two screws for connecting the wires of the light-carrier with the conducting wires of the galvanic battery. The tunnel for the circulating water is connected by an india-rubber tube with an irrigator, which, filled with cold water, is fixed at about three feet above the apparatus, either to the wall of the room or by an iron bar rising from the apparatus. From this irrigator the water runs through the rubber tube into the tunnel underneath the platinum wire; another tube conducts the water from the light-carrier to a hard-rubber or tin box into which it finally drips. On closing the galvanic current the platinum wire becomes incandescent, producing a strong electric light. The heat of this glowing wire is cooled by the cold water circulating in the tunnels beneath it. The light-producer may either be an accumulator or a chromic-acid battery. A rheostat enables us to control the strength of the current.

Under the supervision of Dr. Kollmann, of Leipzig, Heynemann modified Nitze's original urethroscope, as shown by Figs. 1, 2, 3, 4, 5, 6, 7. These alterations have made the urethroscope more easily manageable and allow an easier employment of other instruments through it, such as probes, urethrotomes, etc.

For the easy introduction of the urethral tube it is armed with an obturator. The obturators for the anterior urethra are straight, those for the posterior urethra have a joint by which they can be made

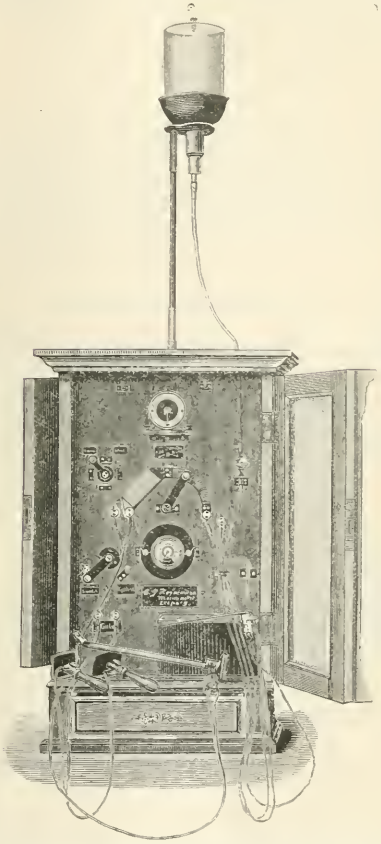

Fig. 7.—Combination Apparatus for Urethroscopy, Cystoscopy, Constant Current, and Electrolysis, constructed by C. G. Heynemann, Leipzig. One of these is in use in the Genito-urinary Department, West Side German Dispensary, New York.

to assume the shape of the Mercier catheter (Figs. 8 and 9).

Fig. 8.—Urethral Tube and Obturator.

Oberlaender also designed a dilating tube with two blades (Fig. 10). For the purpose of probing the

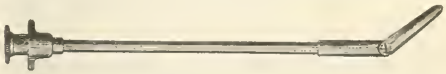

Fig. 9.—Jointed Obturator for Posterior Urethroscopy.

urethral glands an endoscopic sound is used (Fig. 11). Another instrument is a capillary aspirator for remov-

Fig. 10.—Dilating-tube with two Blades.

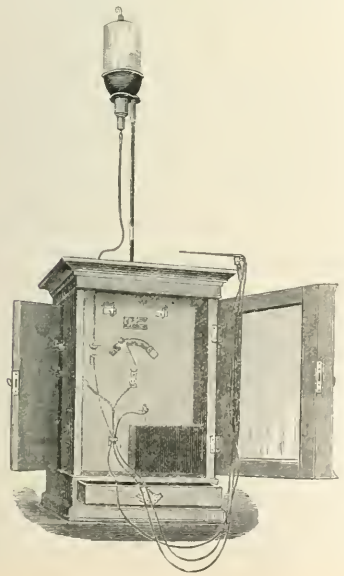

Fig. 6.—Electro-urethroscopic Apparatus with Accumulator.

ing such thin liquid as may be found in the urethral canal (Fig. 12). For the purpose of removing mucus or pus from the glands a spatula has been constructed (Fig. 13).

Of the instruments used for endoscopic treatment

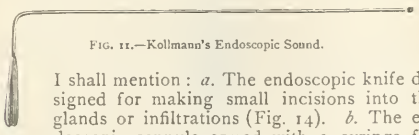

Fig. 11.—Kollmann's Endoscopic Sound.

I shall mention: *a*. The endoscopic knife designed for making small incisions into the glands or infiltrations (Fig. 14). *b*. The endoscopic cannula armed with a syringe for injections into the urethral glands or other orifices (Fig. 15). *c*. An urethral forceps for the removal of

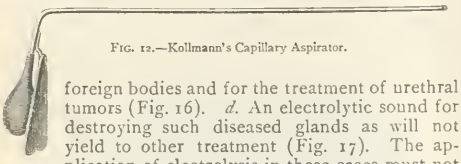

Fig. 12.—Kollmann's Capillary Aspirator.

foreign bodies and for the treatment of urethral tumors (Fig. 16). *d*. An electrolytic sound for destroying such diseased glands as will not yield to other treatment (Fig. 17). The application of electrolysis in these cases must not be confounded with the operations of Foot, of Paris, Robert Newmann, of New York, or Lang, of Vienna, for

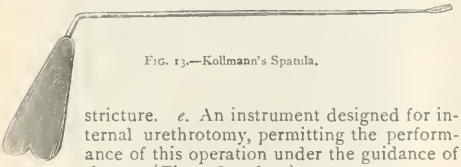

Fig. 13.—Kollmann's Spatula.

stricture. *e*. An instrument designed for internal urethrotomy, permitting the performance of this operation under the guidance of the eye (Figs. 18 and 19).

All these instruments can be used through the endoscopic tube, while the electric light enables us to supervise the field of operation.

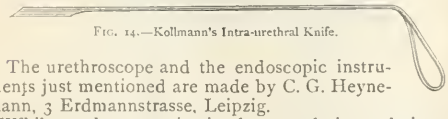

Fig. 14.—Kollmann's Intra-urethral Knife.

The urethroscope and the endoscopic instruments just mentioned are made by C. G. Heynemann, 3 Erdmannstrasse, Leipzig.

While urethroscopy is simple enough, its technique merits somewhat detailed attention. Before introduc-

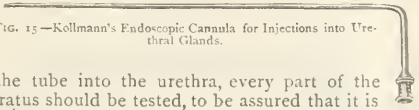

Fig. 15.—Kollmann's Endoscopic Cannula for Injections into Urethral Glands.

ing the tube into the urethra, every part of the apparatus should be tested, to be assured that it is in working order. The water must be in circulation through the soft-rubber tubes and through the light-carrier. This being the case, the rheostat must be turned on until the platinum wire becomes sufficiently incandescent to give a good white light and no further, lest the wire be burned through. Should this happen to the novice the rheostat must be turned back to reduce the galvanic current. Then pressing the two ends of the platinum wire together with a pair of forceps, they will be reunited by turning on the rheostat sufficiently, only until the platinum wire becomes of a red heat.

Thorough examination of the urethra naturally depends upon the neat adjustment of all parts of the apparatus. Of these the platinum wire, whose incandescence furnishes the light, requires that its ends, which are inserted into the light-carrier, be not loose, but rest firmly in their sockets. Should carelessness allow such a condition to prevail, the light will flicker and go out. The same disturbance can be produced by any defect in the battery or the conducting wires.

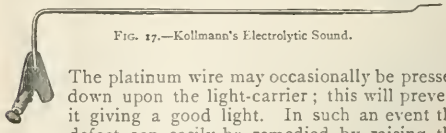

Fig. 17.—Kollmann's Electrolytic Sound.

The platinum wire may occasionally be pressed down upon the light-carrier; this will prevent it giving a good light. In such an event the defect can easily be remedied by raising the wire from contact with a bit of stiff paper drawn beneath the wire and the plate.

The whole apparatus being in perfect order and the water turned on, the patient is ordered to empty his bladder. Any urethral discharge that may be present having been washed away with a syringe, the patient is then placed on the examination chair. If the patient be very sensitive it will be advisable, before introducing

Fig. 18.—Oberlaender's Tube for Intra-urethrotomy.

the urethral tube, to inject 1 or 2 grammes of a three per cent. or five per cent. solution of cocaine. By closing the external orifice the patient retains the injected cocaine in the urethra, and by gentle rubbing spreads it over the whole urethra.

When it is intended to examine the posterior urethra it will be well to use stronger solutions of cocaine with an injector for this part, such as an Ultzmann syringe.

Although the application of cocaine to the urethra is generally borne well, it still requires care. I generally

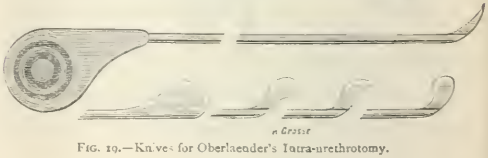

Fig. 19.—Knives for Oberlaender's Intra-urethrotomy.

use a three per cent. or five per cent. solution, and inject as little as possible. Kollmann's little syringe made for this purpose will be found very useful. In the majority of cases cocaine is not needed, but in private practice it will be better to use it, as patients appreciate the physician's skill more if an otherwise disagreeable examination be made painless.

After the urethra is cocainized, endoscopic tube No. 23 may be introduced, the larger sizes being reserved for later use. I lay particular stress upon this point,

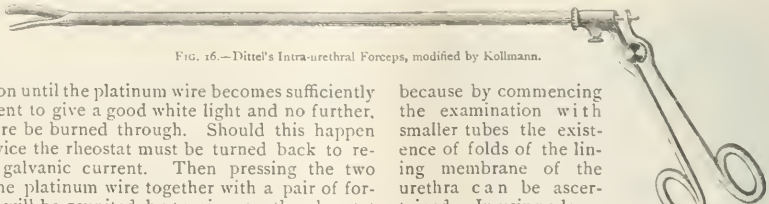

Fig. 16.—Dittel's Intra-urethral Forceps, modified by Kollmann.

because by commencing the examination with smaller tubes the existence of folds of the lining membrane of the urethra can be ascertained. In using a large tube at once these folds may be stretched and appear obliterated during the examination. An error in diagnosis may be the consequence, as will be shown later on. The endoscopic tubes must be lubricated with ten per cent. or twenty per cent. boro-glycerine before

passing them into the urethra. In case a stricture prevents the introduction of the tube, it is better to withdraw the instrument instead of forcing it through the stricture. After dilating the stricture the completion of the examination will be easy. If the meatus is too narrow for the passage or the tube, the defect may be easily corrected by some dilatation or by meatotomy, if there be reason at all to make an endoscopy.

After the endoscopic tube is introduced to the bulb, the obturator is withdrawn. All superfluous glycerine, or mucus, or blood has to be removed with cotton wool twisted round a probe or similar instrument. If this be omitted the electric light will be disturbed by steam, or the mucus or blood will obscure the view. The urethra being dried, the light-carrier is put into the tube and fixed on the spur by the screw provided for that purpose. When the mucous membrane which presents at the end of the tube has been carefully examined, the tube, with the light fixed as above described, must be slowly drawn out of the urethra, care being taken that it be kept in the urethral axis, unless a special part requires particular examination.

While at a cursory first glance the Nitze-Oberlaender apparatus may appear cumbersome and complicated, a few moments' impartial examination will show it to be exceedingly simple. The expense may, too, seem an objection, but when it is considered that 200 marks (£10—$50) will cover an outfit applicable to all purposes, and that spare-parts are very cheap and rarely required, this feature is minimized. But, beyond all, even were the apparatus and its management difficult and requisite of special skill, the clear aspect it gives of diseased regions of the urethra and the facility it offers for their direct medical and surgical treatment, would outweigh all possible objections.

One of the objections that have been made against the Nitze-Oberlaender urethroscope merits brief notice. It is that the introduction of uncovered electric light six inches into the urethra, makes the tube unbearably hot. It has been my pleasure to demonstrate the apparatus to very many medical men from all parts of the world at my Polyclinic, 4 Breitestrasse, Berlin. They have witnessed the light resting in the urethra (without cocaine) for as long as ten minutes and over, while the patient either related his history or looked on indifferently. Then, without turning off the light, I have withdrawn it from the urethra and placed the tube with the light upon the palmar surface of the wrist of the gentlemen about me, with but one result. All expressed unfeigned surprise that the tube with its contained light conveyed nothing further than the normal body temperature. But even were a material rise of temperature the result (which is not the case with the Nitze-Oberlaender), it would more than compensate the interruptions in the examination which it would exact. It must be manifest to even a moment's thought that distinctness of vision is in direct relation to illumination. The nearer the light to the object to be examined, the clearer the object must appear. The Nitze-Oberlaender urethroscope places the light at, almost into, close contact with any part of the urethra, while all other urethroscopes reflect light into the canal; the source of light then being ten, at least six, inches from the site to be examined. All other arguments against the Nitze-Oberlaender fall of their own weight, and therefore require no discussion here.

The diagnosis of pathological changes in the urethra premises a knowledge of its normal endoscopic aspect. This varies individually according to the width and length, *i.e.*, the calibre of the urethra, and according to the blood-supply of its mucous membrane. Thus a normally anæmic urethra appears pale and rosy; a slightly hyperæmic urethra looks distinctly red; while a normally hyperæmic mucous lining is of a purple color.

In considering the normal color of the mucous membrane, it must be borne in mind that it is subject to modifications by the pressure of the endoscopic tube; this artificial appearance must be distinguished from pathological changes which cause similar discoloration. The application of cocaine will also to a degree affect the color of the mucous membrane, by making it appear somewhat anæmic. It will not be found difficult to learn to exclude any errors on these scores.

In looking through the urethroscope the first thing seen is a more or less highly colored disk of mucous membrane. This, in closing in over the objective end of the tube, forms a funnel or circle of mucous membrane which presents for careful observation, 1, a rim; 2, a central figure; 3, an intervening surface. The rim or edge of the funnel generally appears more or less whitened by the pressure of the margins of the open tube.

The central figure is the lumen of the urethra. Its shape varies in the different parts of the urethra, appearing as a semilunar opening in the bulbous portion, as a dimple in the pars cavernosa, and round, or oval, or T-shaped in the glans. A number of longitudinal folds radiate from the centre of the mucous membrane; these are of great diagnostic importance. Their thickness indicates whether they are infiltrated and the degree of such infiltration. Many cases present longitudinal red stripes; they indicate a non-infiltrated mucous membrane. Normal mucous lining of the urethra shows everywhere an equally smooth and glistening surface with a net-work of small vessels.

In drawing out the endoscopic tube the openings of the urethral glands (Morgagnian crypts) present as red depressed specks or small slits of the calibre of a pin's head along the roof, the surrounding mucous membrane being normally smooth or slightly elevated. Very prominent or gaping glandular openings, surrounded by a deeply colored mucosa, indicate pathological conditions which will be considered in their proper place. The number of these crypts varies, under normal conditions, from three to eight. An accumulation of glandular openings in groups indicates pat ological changes.

Endoscopy of the posterior urethra is very rarely practised, partly because it sometimes is painful, and partly because it causes some hemorrhage. These not only interfere with the examination and are out of proportion to the benefits which could result from such examination. Still, when necessary it is easily accomplished by introducing the endoscopic tube armed with the elbowed obturator till it enters the pars membranosa. In lowering the outer end of the tube below the horizontal it is gently conducted into the bladder. Withdrawal of the obturator will naturally be accompanied by an escape of urine through the tube. After gently drawing out the tube until no more urine appears, the liquid still remaining in the tube is carefully mopped up. Then, on inserting the light the colliculus seminalis appears in the field of vision as a round, reddish, pea-sized body. In many cases the openings of the prostatic and ejaculatory ducts can be seen. The peripheral continuation of the caput gallinaginis presents as a more or less prominent ridge of mucous membrane.

In studying the anatomical changes of chronic urethritis as presented by the urethroscope, we find in all stages of the disease two pathological processes: 1, Alterations of the epithelial layer; 2, pathological changes of the urethral glands. The epithelial layer normally forms a smooth, transparent covering of the mucous membrane, having a distinct uniform lustre. This lustre will be increased if the mucosa be congested and swollen; it will be diminished when the mucous membrane is infiltrated. To avoid errors it is necessary to know that an augmented lustre of the epithelial stratum can be artificially produced by some liquid left on the mucous membrane, such as glycerine, cocaine, or mucus, or urine.

Increased lustre of the epithelial layer is found in all cases of subacute superficial urethritis. The more infiltrated the mucous membrane becomes, the more faint its lustre will certainly be; the same holds good in epithelial desquamation with or without infiltration. In some parts the epithelium may be entirely lost, leaving patches of easily bleeding granulations or small ulcerations. In the severer forms of infiltration of the mucosa, the epithelial layer not only loses its smoothness and lustre, but becomes uneven and scaly; it turns opaque and grayish as if covered by a veil. Sometimes the lining membrane is covered with snowy white adherent patches, varying in size from a pin's head to several centimetres in dimension. On account of the similarity of this condition with psoriasis mucosæ oris, Oberlaender calls it psoriasis mucosæ urethralis.

The pathological changes of the urethral glands are divided into two classes, according to their structure and situation. If glandular orifices are visible in numbers the glands manifestly are diseased. *Pari passu* with the severity of the inflammation of the whole mucous membrane, the epithelial layer is destroyed, and thus the orifices of the diseased glands exposed as little red specks mostly arranged in groups.

Oberlaender also diagnoses sub-epithelial glandular inflammation, in which cases the orifices remain invisible. The epithelial layer covering their outlets has a dull, dry, lack-lustre appearance; sometimes desquamation takes place.

The Morgagnian crypts are visible in all forms of chronic urethritis. A solitary diseased crypt very rarely appears on a rosy, otherwise normal, mucous membrane; usually several crypts are found affected at the same time. In the milder degrees of inflammation their orifices appear as small red specks with swollen, puffy walls. Now and then a watery or milky or purulent discharge oozes from them. In the severer forms of gonorrhœal disease, with consequent infiltration around the crypts, their orifices gape and often are surrounded by a puffy red, prominent wall, distinctly marked against the neighboring tissue.

The orifices of the crypts are seldom closed; the inflammation assumes a follicular character and remains in this condition for a long time. Endoscopically we then see a small reddish prominence in the mucosa with a little dimple in its centre, while the lumen is invisible. These encapsuled crypts can be felt by the finger as small, hard nodules.

To be able to understand and diagnose pathological changes of the urethral mucosa in chronic urethritis by means of the urethroscope, it is of importance to remember the histological process in chronic gonorrhœa. All chronic gonorrhœal affections of the urethra are circumscribed and irregularly bounded. The principal seat of the disease is in the pars cavernosa urethræ, or in the anterior part, the bulb being apparently less often affected. The salient histological feature in chronic urethritis is cellular infiltration of the sub-epithelial connective tissue, with a tendency to fibrous transformation thereof. In the milder forms we find the sub-epithelial tissue impregnated with a more or less dense infiltration, consisting of mononuclear or epithelioid cells or leucocytes, which either remain in the upper layers of the sub-epithelial tissue or extend to a greater depth. If these cellular infiltrations cause only a swelling and hyperæmia of the mucous membrane, with no tendency to transformation into hyperplastic connective tissue, the condition is diagnosed as the first form of chronic urethritis, the urethritis mucosæ of Oberlaender. Gradually the cellular infiltration around the Morgagnian crypts and Littré's glands becomes condensed. The epithelium of the urethra being swollen and in a state of desquamation, now changes from cylindrical epithelium into pavement epithelium.

The second form of chronic urethritis is characterized by a denser and deeper cellular infiltration, containing not only leucocytes but also numerous young connective-tissue cells. Whenever the cellular infiltration has gone over to the formation of new fibrous tissue, the urethra appears to be embedded into a rigid mass. The increasing fibrous tissue finally forms a callous cicatricial girdle around the lumen of the urethra. We call this second form of chronic urethritis areal infiltration (Herdinfiltrat). Naturally these different stages of sub-epithelial infiltration modify the endoscopic picture of the mucous membrane.

In the first stage, when only cellular infiltration has taken place, we find an increased lustre of the lining membrane. In cases of denser cellular infiltration the lining membrane has a dull, uneven appearance. The diseased area appears redder than the normal mucous membrane, which becomes swollen and puffy. The longitudinal folds are not slender as in the normal state, but coarse and broad. Instead of 6 to 10 smaller folds we find but 4 to 6 in the central figure. The longitudinal stripes have entirely disappeared. The Morgagnian crypts have swollen, inflamed orifices; occasionally secretion oozes from them. Littré's glands are not visible. When they appear in the field of vision, however, the disease is in a progressive stage. All these changes are irregularly circumscribed. We call this stage of the disease urethritis mucosæ, or soft infiltration.

Endoscopy of hard infiltration will naturally show very various forms according to the advance of transformation of the cellular infiltration into fibrous tissue. With regard to the affections of the glands we subdivide the hard infiltrations into two classes. In the first the glandular hard infiltrations, the orifices of Littré's glands and of the crypts are always visible, as they are more or less inflamed. The second variety of hard infiltrations, the so-called dry form, shows no or but few glandular orifices, they being covered by a layer of epithelial and connective tissue. A dry, dull appearance of the epithelium is characteristic in these cases.

On introducing the endoscopic tube in a case of hard infiltration a resistance by the urethral wall is felt. The central figure appears as a wide gaping funnel. The longitudinal folds as well as the longitudinal stripes have disappeared. The lining membrane has a more or less grayish color. The denser the fibrous tissue has become, the more the whole urethra will have the look of a rigid canal; in the worst form it shows white cicatricial tissue.

If Littré's glands are visible their orifices will be seen in groups, as red inflamed spots in a grayish discolored mucous membrane.

The Morgagnian crypts gape, their lumen is remarkably distended, often surrounded by an inflamed wall, which distinctly shows against the infiltrated, discolored neighborhood.

In the dry form of the hard infiltrations Littré's glands are invisible. The epithelium has a particularly dry and dull appearance, desquamating in spots.

A careful study of such cases will reveal the difference between the various degrees of these hard infiltrations. Thus we can diagnose hard infiltrations of minor intensity, those of a medium degree, and hard infiltrations of the severest forms going over into callous stricture. In comparing such cases it will become clear that between chronic gonorrhœa and stricture only a gradual and not a distinct difference exists. Even in cases of stricture we are able to ascertain if it depends upon a glandular or a dry follicular form of urethritis.

The various stages of restoration, as they occur in the diseased urethra under appropriate treatment, can be followed endoscopically. If a chronic urethritis has been perfectly cured the urethra will have the following aspect: the epithelial layer will grow smooth with normal lustre, normally folded mucous membrane with

a normal healthy color; the crypts and glands cease to be infiltrated, but they may still be visible; and existing cicatrices become smooth and even.

As has been suggested before, urethroscopy of the posterior urethra should not be employed save when required. It is contra-indicated in all cases of acute or subacute posterior urethritis, in tuberculous cases, and in hypertrophy of the prostate. In sexual neuroses or in chronic posterior urethritis endoscopy of the posterior urethra will often be found useful.

In chronic posterior urethritis we also distinguish between soft swellings of the mucous membrane and hard infiltrations, the former being the rule while hard infiltrations are rare. In soft infiltrations the mucous membrane has a purple or cyanotic color, is swollen and of an increased lustre; especially the crest of the urethra and its peripheral continuation show these pathological changes; the parts bleed easily. Hard infiltrations of the posterior urethra only develop after long continual swellings of the mucosa, which then appears pale, grayish, dry, and lustreless. The caput gallinaginis also has a pale yellowish color, a dull lustre, and is not prominent nor wrinkled, but flat and smooth.

Of tumors of the urethra we mostly find papillomata, now and then fibrous polypi, and very rarely carcinomata. Papillomata and fibrous polypi can easily be diagnosed with the urethroscope. The removal of these growths will often cure an otherwise untractable gleet. Oberlaender was the first to diagnose carcinoma of the urethra by means of the urethroscope.

The diagnostic value of urethroscopy having been demonstrated, its therapeutic advantages merit consideration. As previously remarked, there is every reason for demanding an exact diagnosis in urethral affections as in all other diseases. Urethroscopy, we have seen, enables us to diagnose the various forms and stages of chronic urethritis; hence it is but logical to expect the abandonment of the routine treatment of chronic gonorrhœa by injections and bougies, and that the case be treated according to differential diagnosis, which urethroscopy makes possible.

Bearing in mind that the principal anatomical and endoscopic feature of chronic urethritis is cellular infiltration of the mucosa, with a tendency to transformation into fibrous tissue, it must be obvious that the ordinary urethral injections are of no therapeutic value. This has been recognized some time ago, and it led to the application of the bougie or metallic sound in cases of chronic gonorrhœa. These instruments are introduced into the urethra for the purpose of dilating it and of causing pressure upon the infiltrated mucosa, in this way effecting a dissolution or melting of the infiltrations. A moment's thought will show the impossibility of attaining this aim by means of the soft elastic bougie, especially in cases of hard urethral infiltrations.

The passing of metallic sounds of various calibre in cases of chronic urethritis is undoubtedly more rational than the application of the soft bougie. The heavy metallic sound, especially if large calibres are used, in many cases answers the purpose of stimulating the reabsorption of hard infiltrations, but not in all. In very many cases a narrow meatus will prevent the introduction of a larger sound than perhaps No. 24 or 26 Fil. Charrière, or even a much smaller calibre. Such a size would then lie quite loosely in the urethral canal without exerting any pressure or dilatation whatever. For this reason various dilators have been devised, which are easily introduced through a narrow meatus and allow dilatation of the urethra to any degree desired. The best dilators are those of Otis, Planer, and Oberlaender, the Oberlaender's dilator being the most useful. While all the dilators have two blades, Kollmann constructed a dilator with four branches for the pars anterior, with the purpose of exerting dilatation of equal force in all directions.

By means of these dilators infiltrations of all dimensions can be broken down, and thus the normal calibre of the urethra restored. But it is evident that true callous infiltrations are no fit objects for dilatation; they must be treated by the other methods which enter into the therapeutics of this form of urethroscopy. If the dilators are used indiscriminately without previous endoscopic diagnosis as to the seat of the infiltrations, dilatations may be continued for months and months without gaining the end in view. Urethroscopy has shown that infiltrations are always circumscribed and not diffuse. Cures can be effected only by directing dilatation to those localized infiltrated places. Is it therefore too great a requirement that all treatment should be based upon correct endoscopic diagnosis?

The Nitze-Oberlaender urethroscope not only guides treatment by dilatations to the very seat of infiltration, but also enables the physician to attack localized gonorrhœal foci through the urethroscopic tube under the guidance of the eye. The endoscopic tubes are sufficiently wide to admit the introduction of other instruments besides the electric light, and enable the practitioner to employ them under direct illumination of the diseased parts. Infiltrated glands can easily be incised with a knife or destroyed with an electrolytic sound: various solutions can be injected into the glands or any openings found in the urethra. Under direct illumination hard infiltrations also can be incised, and even internal urethrotomies performed. The endoscopic tubes will also allow sufficient room for the removal of urethral polypi by means of the snare or forceps. All this can be done, and must be done, under the supervision of the eye. Whoever will test the applications of these instruments through the endoscopic tube will find no difficulty in handling them.

It is beyond my hopes that this little effort will give the urethroscope a place among the general practitioner's instruments of precision and treatment; an abler pen than mine would be required for such a desirable end. But it is my hope that at least those specialists who have as yet not used the instrumentarium I have herein mentioned, will be led by these crude lines to investigate. Their work then will serve to tear urethral diseases from the realm of that crass empiricism which, sadly enough, has too long enveloped them. If my labor brings about only investigation, my ambition will be more than gratified.

In conclusion I desire to perform a most pleasant duty. It is to thank those gentlemen from England, America, and the British Colonies who have honored me by becoming my pupils, for the incentive they gave me to condense herein the salient points of my clinical lectures. Thanks also are due to my friend Ferdinand C. Valentine, M.D., of New York, for valuable suggestions regarding the arrangement of this little article.

May 30, 1895.

Amputation of Omentum in Hernia.—1. All irreducible hernias should be operated upon unless contra-indicated by age or condition of the patient. 2. All omentum found outside the abdomen, or that will protrude under gentle traction, should be removed. 3. Multiple, independent ligatures of good-sized silk, which surround the vessels alone, or small pieces of fatty tissue, are believed to be safer than other methods. 4. The use of some film-forming substance, as aristol, on the stump is believed to protect in a measure from subsequent adhesions.—De Garmo.

Absorption of Ligatures.—In four hundred experiments it was found that, in from one to two years, seventy per cent. of catgut ligature had become absorbed; thirty-six per cent. of silk, sixty-six per cent. of hemp or flax, and twenty per cent. of horse-hair. Order of rapidity; catgut, hemp, silk, horse-hair.—Porta.

Insomnia.—Asafœtida is a valuable remedy in the insomnia occurring in the aged.

ARE WORK AND WORRY CAUSES OF NERVOUS AFFECTIONS?

By L. HARRISON METTLER, A.M., M.D.,

CHICAGO, ILL.

Much stress is laid by authors upon overwork as a cause of nervous troubles. On the other hand, Dr. Clifford Allbutt says, in a recent popular essay, that as excitation is the function of normal nerve-cells it is hardly conceivable that their injury should be brought about by simple excitation. It is not to be denied that neurasthenia is a palpable reality, and that it is an accompaniment of modern civilization. The genuine neurasthenic, with his restlessness, insomnia, absent-mindedness, weakened memory, languid expression, drawling speech, tired gait, lack of enthusiasm, tendency toward pessimism, headache and other aches, dyspepsia, constipation, and general malaise is too visibly among us to deny his existence. There are those who declare that our modern civilization, with its high-pressure mode of life, its sharp competition, its exhausting round of amusements, its rivalry of wealth, its fads, follies, and fashions, its sensationalism, its superficiality and mental boulimia, its self-indulgence, luxury, and unnatural stimulation, is responsible for the increase of nervous troubles. They say we must retract and put ourselves under greater restraint; we must return to a Spartan simplicity, and we must live a less sensuous life, cultivating more and more the homely pleasures of a rustic existence. All of which is undoubtedly true and has been preached by poet and philosopher from Hesiod to Thoreau. On the other hand, there are not wanting advocates of a still greater stimulation of human nerve-force. They believe that man is capable of a still higher civilization and that science is going to give him possession of yet greater power over nature. In the attainment of this desirable climax they hold that the weaker existences must necessarily be eliminated, simply because of their incapability to keep up with the rapid march of events.

In the struggle of mind over matter some must obviously be led astray or be oppressed by the unwonted glamour of the new conditions. Many nervous systems must be shattered and ruined in their futile effort to accommodate themselves to the swift change. The works of genius, the creations of art, the discoveries of science, are all the result of highly stimulated nerve-force. Rousseau's idea of the normal man is not the right idea, for if man is to remain in a blissful state of barbarism, civilization and his high destiny would be impossible. Advancement comes only from competition, and competition involves an ever-increasing stimulation of nerve-force. Barbarous races dwindle away and ultimately vanish in the presence of civilized man because they cannot compete with his superior intelligence. If they attempt to compete, they are quickly overwhelmed, and their constitutions are undermined by the too sudden alteration of environment. In somewhat of a similar way we are approaching a higher state of civilization, and many a constitution is being broken down because of its unprepared condition to meet the rapidly changing environment. Neurasthenia is to a large extent the cry of the weaker nervous systems, that they are being left in the rapid advancement of the race. They are struggling hard and valiantly to keep up, but all without avail. It is a question, then, whether human progress shall stop and turn back in their behalf, or continue onward in its career and leave them to their fate. Must electricity and steam be abolished that the nerves of neurasthenics be relieved of the harrowing excitement of high speed? Must grand opera, great commercial enterprises, and magnificent feats of skill and genius remain unattempted because a certain number of nervous systems are incapable of maintaining their healthy equilibrium in the presence of such vast undertakings? Most assuredly not, answer the advocates of the higher advancement for the human race. Let nerve-force be even more stimulated, they say; let man continue to strive after his loftiest mental and physical ideals; that is the very purpose, the *raison d'être*, of nervous matter. Civilization and the increased stimulation of the world's nerve-force proceed *pari passu*; if nerve-force fails it must be regenerated in some other way than by the checking of competition and human progress. Thus argue the two opposing factions in regard to the causes and amelioration of the neurasthenia so prevalent at the present day. Both explanations have an element of truth in them; but neither, it seems to me, has yet accounted for the great excess of neurasthenia that exists in our midst, and daily flocks to the offices of our noted neurologists.

As I do not purpose to consider here such physical causes of neurasthenia as autoinfection, toxæmia, reflexes, traumatisms, etc., but rather the psychic causes and causes originating in vicious habits, I will at once enter *in medias res* by considering for a moment the modern physiology of the nervous apparatus. In the most recent conception of the cerebro-spinal system of nerves impulses originating in the cerebral cortex are as much peripheral as those starting from the skin. The direct sensory-motor centres are to be found in the spinal cord and basal ganglia. The cortex is a general centre for the representation of motor and sensory images. Psychosis is a sensory-motor phenomenon and mentalization is the result of the combined activities of the cortical, sensory, and motor areas. Voluntary action, therefore, is as much a reflex as an ordinary involuntary spinal reflex. Removal of the cerebral hemispheres, olfactory ganglia, optic lobes, corpora striata, and optic thalami results in a loss of intelligence, of inhibitory rationality, but the animal still executes purposive movements which are somewhat different from the simple reflex acts depending upon the spinal cord. In 1876 Hitzig spoke of the effects of cortical lesions in the motor area as "the expression of an abnormal representative action;" in other words, as the result of a destruction of the motor images belonging to certain voluntary movements. The muscles of the animal are not paralyzed, but the animal no longer possesses any mental images as ideal representations of the movements it should make or desires to make. The condition, roughly illustrated, is probably somewhat like that of the nightmare, in which the victim is more or less conscious of his surroundings and is full of a desire to move, but is nevertheless incapable of action or acts only automatically.

Munk's theory is popular in Germany and affirms that the activity of the cortical sensory-motor areas results in "conceptions of movements" rather than movements themselves. Franck inclines to the theory of a reflex action in the motor areas. Marique adopts somewhat this reflex theory for the motor cortex. Schiff's theory in regard to the cortex is that of a pure reflex. Many authorities among British and continental experimenters could be cited to show that the cerebral cortex does not act directly upon the external sensory muscular apparatus of the body. Though there is considerable obscurity in regard to the real functions of the basal ganglia, and in regard to the mental relations among themselves of the sensory and motor areas of the brain, there is almost a unanimous opinion, based upon the closest study, that the gray matter of the cord (and possibly of the basal ganglia as well) is the direct centre from whence pass the motor impulses to the muscles and sensory impulses to the brain. The idea of a certain desired movement originates somehow in the cortex: a certain set of cells are started into activity and send forth an impulse to the cells in the anterior horns of the cord. These cornual cells receive the impulse, transform it, and send it out to the appropriate muscles for the production of the required movement. In the same way the prick of a

pin is felt somewhere on the surface of the body and the sensory impulse is transmitted to the gray matter of the cord. Here it is transformed and sent up to the sensory cells of the cortex, which interpret the nature of the original impulse. In both instances the brain acts more as the interpreter of the motor and sensory impulses. In either case the brain has remained relatively quiescent, and both the motor and sensory impulses have been reflective in the cord. These facts are so well known that I only refer to them in the briefest possible manner. The reason that I refer to them at all here is to show that the cerebro-spinal system resembles a balance, with its fulcrum in the intermediary gray matter of the cord and its two armatures, the cerebro-spinal system of nerves and nerve-cells on the one hand, and the spino-musculo-cutaneous system on the other. The former, roughly speaking, is psychical in character, or has to do with impulses that partake of purely mental characteristics, while the latter is more strictly organic in character and is somewhat of a mere connecting link between man's ego and the external world. Of course there are many details not entered upon here, and this conception of the cerebro-spinal apparatus is only presented coarsely for the purposes of the present essay.

Accepting, then, for the nonce, this twofold conception of the cerebro-spinal system, the internal or mental or psychic on the one hand, and the external or organic or musculo-cutaneous on the other, I wish to show that a want of proper balance between the two, rather than the mere overwork of the entire system, is the real cause of much of the modern neurasthenia. And if I can succeed in doing this, not the least of the advantages will be that certain suggestions will naturally present themselves to the mind of the reader for the relief of the trouble.

It is an old saying that genius and talent are but synonyms for industry and an unusual capacity for work. Dr. Clifford Allbutt has said that in his extensive observation he has rarely seen a case of mental break-down from simple overwork, provided the individual originally had a normal nervous system free from hereditary taint. In almost every instance of insanity seen by him attributed to prolonged nervous strain there was some inherited weakness, bad mode of life, or other cause beside the mere overwork. Clearly, therefore, the work, while being an active cause, should not be regarded as the sole or even the important cause. Every once in awhile, however, there are genuine cases of neurasthenia in whom there seems to have been an originally strong and healthy physique, but in whom overwork has been, so far as we can see, the real and only cause of the trouble. In such cases I have almost invariably noticed that it was not the overwork alone that initiated the nervous break down, but rather the monotony of that work. To illustrate: A pianist practises upon his instrument say eight hours a day, and does almost absolutely nothing else in the way of a physical or mental offset during the hours that he does not practise; in a short time neurasthenia results. On the other hand, another pianist of apparently equal physique and nerve-force also practises eight hours a day in divided intervals, and when not practising turns all his energy to some other pursuit, mental or physical; he continues for years and never shows the least indications of neurasthenia. Neurologists have all seen such examples, and they are well illustrated in the lives respectively of Schumann and Mendelssohn.

I was recently told by a distinguished concert-singer, educated for many years abroad, that the reason a great many vocalists never get beyond the amateur, though they may have marvellous vocal powers, is that they practise singing aloud too long a time at once, and so completely exhaust their voices and nerve-force. For this reason many of the continental teachers are telling their pupils to practise their singing mentally, that is, to hold the music and read it without making a sound with the vocal cords except occasionally. I see in this method not a diminution of actual work done, but a decided relief in its monotonous character.

Many artisans use their hands more than does a telegraph operator, but the latter is the one who suffers from the cramp, because of the persistent monotony of his work.

The introduction of machinery and the specialization of work, chiefly brought about in the great factories, has not increased but rather lessened the actual work done by the operatives. Nevertheless cramps, neurasthenia, and a dozen other functional ailments attack the latter that were quite unknown to the hard-working all-round mechanic of former days. The great majority of the modern factory employes are either unable or unwilling, through ignorance or weariness, to offset the monotonous strain to which they are subjected by appropriate mental relaxation. One side of their nervous apparatus is therefore in more or less of a dormant state, while the other is stimulated or exercised to an unusual degree.

Among students, scientists, professional men, and brain-workers generally, the same condition obtains upon the other side of the nervous apparatus. With them, instead of a monotonous series of external impulses pouring in upon the reflex centres of the cord, the impulses are sent down, in the representative form as it were, from the cortex to the spinal centres, but there they end without their appropriate outlet in musculo-cutaneous activity.

The romance writer, for instance, like the unfortunate Marie Corelli, who leads more or less of an arduous sedentary life, exercising her imagination with all sorts of real and unreal visions, stimulates but one side of her nervous make-up, leaving the organic side more or less dormant and subject to unfulfilled impulses. Every form of prolonged mental strain, without a complementary relaxation in some form of physical activity, necessarily disturbs the balance between the psychic and organic sides of the nervous system. It is this prolonged breach of balance rather than the mere quantity of work done that acts disastrously upon the nerve-centres. For this reason the introduction of athletics, when properly graded, into university life has been of advantage to the average student. Consider the life and work of Oliver Wendell Holmes, who lived an all-round existence full of out-door pleasure as well as of mental strain, and one will have an admirable illustration of a well-balanced nervous system tending toward health, optimism, and good old age. I was once told by a friend that one evening he happened to be in a room adjoining one occupied by Paderewski, and that out of mere curiosity he took the trouble to note that during one of his practising periods this distinguished pianist executed a particular cadenza without a moment's cessation something like seven hundred and fifty times. Is it any wonder this artist at the end of the season suffered an attack of nervous prostration! The one-sided monotony of such an exercise would disintegrate any normal nervous matter.

The increased responsibilities necessarily associated with our higher civilization and keener competition produce an excess of worry. To this worry has been attributed much of our modern neurasthenia, and justly so, but the worry which is usually associated with neurasthenia is the result rather than the cause of that trouble. It is the expression of an unbalanced nervous system, the cry of the nerves and nervous elements on the psychic side for more rest or more exercise to restore the normal equilibrium of the whole. There is a form of worry, however, which is unavoidable and is a cause rather than a result of neurasthenia. It is the accompaniment of a highly organized nervous apparatus, is to a certain extent normal, and is sometimes otherwise known as over-anxiety. To tell a man who is involved in a vast enterprise not to worry be-

cause of certain changing conditions would be about as sensible as to try and persuade a miner entrapped in a caved-in shaft to keep cool and not get nervous. Accidents and responsibilities bring fear and anxiety, and these in turn produce worry. Such worry is involuntary and reveals an over-excited condition of the psychic side of the nervous system. It can be borne for a time, but if not counteracted by some complementary exercise of the other side, the organic, it sooner or later results in a disastrous breach of balance and neurasthenia. It isn't the worry, or even the excess of it, that harms, but the monotonous continuation of it. The occasional manifestation of this worry is in fact a wholesome sign, for it shows a commendably sensitive nervous organization. The orator, for instance, who experiences a feeling of over-anxiety before he appears in the presence of his audience is likely to develop into a greater speaker as he goes on in life than the one who is so stoically indifferent as to feel no nervousness at all. As physical pain is man's greatest protector by teaching him to be more guarded in the future, so mental anxiety up to a certain point is his benefactor in causing him to avoid, if possible, the mistakes of the past. Just as the continuation of physical pain ends in physical breakdown, so the continuation of worry terminates in the ruin of the nervous system.

Work and worry, I therefore take it, are not baneful in themselves, not even when carried to excess, but the monotonous, unbroken continuation of the excess is exceedingly injurious. An occasional break in the equilibrium of so delicately a balanced organization as the human cerebro-spinal nervous system is not only necessary but often extremely commendable. Only in this way can individual and racial advancement be accomplished. But too long maintenance of the rupture of equilibrium terminates, as we see all about us, in the most unfortunate results for the nervous system.

The corollary of all this is almost too obvious to need repetition. In the management of neurasthenia failures are notoriously frequent, and very largely, I believe, because the trouble is not viewed from the above stand-point. Absolute rest is frequently as uneffective in restraining an overwrought nervous system as the whole gamut of nervines, stimulants, baths, massage, and electricity. How often has the mistake been made of sending a patient broken down with an excess of business care and anxiety away to some lonely mountain resort ; or of recommending some pampered daughter, living a quiet life in a small town, into the midst of the unwonted glare and whirl of some fashionable summer resort ! An athlete must keep up his training, but it must be regulated ; so a hard student should not be deprived entirely of his books, but his physical relaxations should be properly intermingled with his studies. Before any general advice is given, before any medicine is prescribed, the daily and almost hourly habits of the neurasthenic should be inquired into. When any monotonous habits or particular nervous strain, mental or physical, are discovered, it is not enough, nay, more, it is generally highly injurious to tell the patient he must give up absolutely such habits. Most patients will answer that that is more easily said than done, and in most cases it is so. On the other hand, the medical adviser must study the nature of those habits and employments and recommend others that counteract or complement them in some way. The athlete must be recommended to take up some line of mental study, and the scholar must be encouraged to adopt some regular form of physical exercise. The monotony rather than the mere amount of their respective occupations must be overcome. The emotional maiden who overindulges her imagination with novels should be recommended to exercise her reasoning faculty more with works of a different character. If she is visionary and given to dawdling away her time in day-dreams, she should be given a few tasks in household drudgery as an offset.

Gardening is a splendid relaxation for a banker. A European trip with the faithful keeping of a diary is a capital outing for the girl who has passed a butterfly existence of a long fashionable winter. Tennis, boating, and all sorts of athletic sports are to be urged for those whose occupations are sedentary and confining. On the other hand, those whose work is largely mechanical and physical should be persuaded to relax themselves by taking up a course of reading, or the study of some language, art, or science. Gardening would be a poor sort of relaxation for the carpenter who has been pushing the plane all day. The commercial traveller would smile at you if you suggested to him that he needed more physical exercise ; so would the shop-walker or the letter-carrier or the insurance solicitor. It is a good thing to suggest to neurasthenics also the authors and books they should read, the kind of amusements it would be well for them to see, the class of friends that they should cultivate. In fine, no detail is unimportant in the management of this prevalent trouble and the details of the moral treatment are undoubtedly the most important. It must always be remembered that a neurasthenic's nervous system is in most cases not so much overworked or underworked as unbalanced. Every suggestion made by the medical attendant must have in view the restoration of this balance. To obtain the best results in the treatment of neurasthenia demands therefore a thorough comprehension of the trouble and a faithful attention to the minutest details on the part of the practitioner. He must be a man quick-witted, full of ready ideas, liberally educated, somewhat of a psychologist, a close student of human nature, conversant with the people and events of his day, sympathetic, social, and positive in character. Such a physician will handle cases of neurasthenia, all other things being equal, better than one who merely prescribes drugs and recommends rest and change.

FŒTAL DYSTOCIA.[1]

Illustrated by a Case of Difficult Delivery of Head, Shoulders, and Adherent Placenta, with Remarks on the Immediate After-treatment of Post-partum Hemorrhage.

By ERVIN A. TUCKER, M.D.,

Resident Physician, Sloane Maternity Hospital, New York City.

So many members of this Society are constantly brought into intimate contact with obstetric cases involving complications of more or less difficulty that no apology seems necessary in presenting before you to-night this paper upon a special subject. The case about to be described has been selected not only because it is in itself an extremely interesting and unusual case, but because it will offer for discussion so many points which are of direct practical value to us all.

This patient was thirty-six years of age ; pregnant for the eighth time. Her first three children were born alive, the next four still. All the children had been large—at least nine pounds in weight. There was much œdema of the extremities in the first and second pregnancies, less in the third, and none subsequently. She was extremely desirous of having another living child ; but, as four in succession had been born dead, she was of course much in doubt whether this could be accomplished. Just why these four apparently healthy children were stillborn I could not learn. She was a woman of very large frame, in good health when I first saw her. Her pelvis was symmetrical and unusually large. Her

[1] Read before the West End Medical Society, June 1, 1895.

last menstruation was June 15th to 20th, and she was sure that she felt life on November 7th. When I saw her, November 22d, the fundus was at the proper height for a five months' pregnancy, and therefore corresponded exactly with the dates of menstruation and quickening. On January 19th the fundus was at the proper height for a seven months' pregnancy, the child, presenting by the breech, was freely movable in the liquor amnii, which was rather more abundant than is usual at seven months.

Three weeks later (February 7th) this patient presented quite another picture—the liquor amnii had increased enormously in quantity so that the fundus was almost at the ensiform, and the position of the fœtus could no longer be made out by palpation ; moderate dyspnœa was present because of the pressure upon diaphragm, and the stomach refused to retain ordinary food. Secretion of urine was scanty, but there were never any evidences of nephritis. I told the patient that it would be necessary to induce labor before long if she became worse. It had been my intention from the first to induce labor before full term, in order to avoid having the child too large for easy delivery and to avoid degeneration of the placenta, which I suspected might have been the cause of the deaths of the previous children, as we know that placental degeneration often occurs in multiparæ at full term, if the children are unusually robust and grow to an enormous size.

On February 16th (nine days after the dyspnœa had begun to be distressing) the patient was brought to the hospital in a desperately bad condition. Her pains had begun the night before at eight o'clock and she was completely in the second stage when admitted at 11 A.M., *i.e.*, duration of first stage of labor had been fifteen hours. Labor had evidently come on because of the excessive abdominal pressure—fundus was at the ensiform, and the abdomen extraordinarily distended and so tense that palpation was absolutely impossible. Dyspnœa was extreme, pulse rapid, temperature high, and her general condition very poor because of the exhaustion from lack of sleep and inability to retain any food. She was quickly prepared for delivery. When the membranes were ruptured, at 11.18 A.M., the position of the child was found to be L. O. P., the head, of large size, engaged in the pelvic brim. It was noticed that the scalp was unusually thick, and seemed œdematous immediately after the rupture of the membranes, when of course no caput succedaneum had had time to form. Child was alive, but the heart could not be heard because of the hydramnios.

The mother's condition was so alarming that immediate delivery was clearly indicated, so forceps was applied at 11.26 A.M. to sides of the head. The wide separation of the forceps handles showed that the head must be very large. With moderate traction, aided by the patient bearing down, the head advanced into the pelvic cavity and the position became occiput directly posterior. The forceps now began to slip badly, when stronger traction was used. As it was necessary, for the mother's sake, to deliver this head as soon as possible, the handles of the forceps were compressed and an increasingly strong traction used, but the forceps slipped just the same. As the head was now completely in the pelvic cavity, with the occiput directly posterior, an attempt was made to rotate the occiput to the front, but this resulted only in the forceps going around till inverted, while the head remained stationary. Hoping that a forceps with a greater divergence between the blades might secure a better hold, I substituted Simpson forceps for the McLane forceps, which had been used up to this time, but this fenestrated instrument slipped with every traction, even when the handles were held tight together. Of course, I had by this time given up all hope of saving the child, for I knew that the skull must have been more or less fractured when the forceps slipped while the handles were compressed. Auscultation showed that the fœtal heart was still beating, but was very irregular. The forceps was removed at 11.47 A.M., because delivery with this instrument was impossible, and further attempts would be a waste of time.

Podalic version seemed indicated now, as forceps had failed and craniotomy of the living child was not thought best, though I must say, in thinking the case calmly over since, that craniotomy was really indicated, if we consider the fact that the skull was already fractured so that the child could not possibly live long even if born alive, and if we give due weight to the advantages gained from not administering chloroform to a patient whose condition was already very bad, and not subjecting her to the shock which is necessary in doing an internal version. Another thing which made me at that time decide upon version was the knowledge that the patient was so desirous of having the child born alive. So chloroform was given to the surgical degree, the left hand was slowly passed into vagina at 11.55 A.M., pushing the head up and off to the left. In the relaxed condition, due to the chloroform, this was not at all difficult, and the head was soon resting in the left iliac fossa. The anterior (right) knee was at once found and a finger hooked into its flexure, but strong traction failed to make the child turn. The leg was then straightened out and a good hold obtained upon the foot, but the strongest possible traction upon this right foot, with upward pressure upon the head, and downward pressure upon the breech, failed to turn. Traction was made upon both feet with the same negative result. The umbilical cord was now felt of at the navel and found to be pulseless, so the child was undoubtedly dead (12.16 P.M.). Death of the child probably explains why the attempts at version failed, for a dead body lacks that resiliency which makes version easy.

Soon after the hand was withdrawn the head came down into the pelvis again. The blades of Tarnier's cephalotribe were then inserted laterally, grasping the head (L. O. P.) over the left side of forehead and the right side of occiput. The blades were screwed so firmly together that slipping was impossible. Repeated tractions, as powerful as could be exerted, with extreme oscillation, laterally and vertically, caused slow advance till the head was born at 12.24 P.M. As the head was being extracted, the occiput was rotated to the front, so as to have a smaller diameter born. During the strong traction necessary for delivery the head burst and most of the brain escaped. Then it was discovered that the shoulders were too large to enter the pelvic brim, though the strongest possible traction, without and with oscillation, was made with the cephalotribe still grasping the head.

The only way now remaining to effect delivery was to diminish the shoulder-bulk, so the head was removed from the body by turning it around completely, thus wringing it off of the neck very easily and quickly, leaving as neat a stump as if the decapitation had been done with a knife. My hand was then inserted and the anterior (right) arm brought down. Traction upon this arm so strong that the shoulder-joint began to separate failed to cause advance, so the other arm was brought down and traction made upon it till it also began to tear in the axilla. By this time the shoulders had come down to the pelvic floor. As no more traction could be made upon the arms, a blunt hook was forced between the ribs near the spine. By very strong traction on this hook the body was finally delivered, back anterior, at 12.46 P.M.

The patient was by this time *in extremis*. The uterus, containing the secundines, was unusually large and flabby. A little blood began to trickle away just after delivery of the child, so an attempt was made to express the placenta in order to prevent further hemorrhage. As this attempt failed, the whole hand was inserted and the placenta found on the right side of the uterus, extending up well over the fundus. This pla-

centa was firmly adherent over its entire maternal surface and had to be dug away from the uterine wall with the fingers and brought out by the handful. This was done as rapidly as possible—in about three minutes. Hemorrhage was profuse all the while. As soon as all the placenta had been extracted, at 12.51 P.M., a hot acetic-acid uterine douche was given, causing the uterus to contract well and remain contracted so that there was no more hemorrhage.

Before extraction of the placenta was completed, the patient was apparently dying; all the symptoms due to great loss of blood were present. Meanwhile a nurse had been giving hypodermics of ether and of brandy—at least a dozen of a half drachm each were given as rapidly as possible, but the pulse remained imperceptible at the wrist. As soon as the uterus was emptied the first hot saline enema was given and the patient soon began to rally slowly. One-half hour later the pulse could be counted (120), and it slowed gradually as the enemata were given. The great value of hot saline enemata after hemorrhage cannot be over-estimated, and their value was especially illustrated in this case. The first enema, consisting of two pints of water at 116° F., one ounce of whiskey, and one drachm of salt, was given at 1 P.M., and followed by another at 1.30 and another at 2.45 and another at 3.45 P.M., then a smaller hot enema (one pint of water, one ounce of whiskey, and one drachm of salt) was given at 5.30 and again at 10 P.M. All these were retained except the last, which was partially expelled. As soon as an enema of this kind ceases to be retained, I take it as a sign that the vascular system has obtained all the fluid it needs to replace the lost blood. In this case there were fully nine pints of saline solution retained and absorbed before the pulse became full and strong, thus showing that no more fluid was needed. The value of the heat carried in with the enema must not be underestimated. When a patient is in deepest collapse, one hot enema will do more good than several warm ones. The salt must not be omitted, if we wish the fluid to be quickly absorbed. A drachm of salt to a pint of water makes a formula easy to remember and is near enough to a "normal salt solution" for all practical purposes. The enema also gives us an easy means for introducing stimulants when the stomach refuses everything, and we thus avoid the inconvenience of hypodermic stimulation.

I run the risk of wearying you with these statements about well-known facts, because I am afraid that in the eager rush for new remedies and new specifics, which is so characteristic of this day and generation, some of us have forgotten, or may forget, the standard value of these simple but always reliable methods of dealing with serious conditions. For several years now I have used hot saline enemata containing various stimulants for the immediate after-treatment of all cases of severe hemorrhage with the result that I cannot report even one fatal case.

During the night following delivery the patient could retain nothing in the stomach. She vomited repeatedly, and retched even when the stomach was empty. This troublesome symptom was finally relieved by giving small doses of champagne and cracked ice, after several other gastric sedatives had been tried in vain. In the afternoon (about twenty-four hours post-partum) she could retain milk and vichy. From this time on her convalescence was rapid and constant, without an unfavorable symptom of any kind.

The chart of her temperature, pulse, and respiration showed that her puerperium was uneventful, except for the wonderful fact that she recovered. She had no afterpains, as she had had in all previous puerperia except the first. She had no headache, which is so common after an enormous hemorrhage. She had no sepsis, which is so apt to follow exhausting labors, especially if there is much blood lost, or if operative manipulations are prolonged. The absence of the headache and sepsis and her smooth convalescence were undoubtedly due to the generous use of the saline enemata. The absence of after-pains was due to the thorough emptying of the uterus. The lochia were normal in quantity from the first, instead of being scanty as is the rule after hemorrhage, but their color was pale. The uterus involuted perfectly. At her own request, because she felt so well, she was allowed up in a chair on the twelfth day and was allowed to walk a little on the seventeenth day.

With your permission I will set before you some rather astonishing figures about this case. Of course you are at liberty not to believe them, but I assure you that they are true. When the membranes ruptured, nine quarts of liquor amnii were caught in pails; a moderate estimate is that fully one-half as much more was lost then and during delivery, as some escaped with every pain, and much more came away, when the attempt at version was made; therefore, the total quantity of liquor amnii was at least twenty-seven pints. The child, a female, though of only about eight months' intra-uterine development, according to the best of my knowledge and belief, measured 56 ctm. in length; the circumference of the shoulders was 43 ctm.; of the abdomen, 45 ctm.; and of the right thigh, 19.5 ctm. The head and body weighed 9 pounds 6 ounces, but all of the blood and meconium and nearly all of the brain were missing; these would certainly weigh 2 pounds (probably more) in such a large child, so the total weight was at least 11 pounds 6 ounces. A necropsy of this child revealed the fact that the peritoneal and pleural and pericardial cavities were full of brownish serum, so the child would probably not have survived long, even if it had been born uninjured. Most of the blood with the placental débris was caught in basins. After the pieces of placenta had been picked out, the blood was found to weigh 93 ounces; a very modest estimate of the blood that was not caught is 12 ounces; so the total blood loss was 105 ounces, all of which hemorrhage took place within five minutes. The placenta weighed 3 pounds 11 ounces. If we add together all that escaped from this patient's body from the time when the membranes ruptured till the uterus was empty, we find a sum total of about forty-eight and one half pounds.

In the operative part of this case there were several practical points demonstrated which, it seems to me, are well worth considering. One lesson of special importance is, that if the forceps slips when properly applied, it means that the case is not adapted for delivery with forceps, *i.e.*, the forceps is contra-indicated and its further use will result only in doing harm. Fenestrated forceps blades slip just as badly as do solid blades, if the head is too large, *i.e.*, any forceps will slip, if it does not fit the head. If the forceps slips while strong traction is being made, the child's skull will surely be fractured. After the liquor amnii is gone, version is always difficult and usually impossible, if the child is dead. When the fœtal heart cannot be heard, feeling of the cord at the navel is a legitimate way of finding out whether the child is alive or dead, if this information is necessary for deciding upon further treatment. If the child must be born head first and forceps cannot deliver, the cephalotribe is the best instrument for obtaining a hold of the head firm enough to accomplish delivery. Oscillation will cause advance when straight traction fails. Pulling down one or both arms after decapitation is the easiest way to deliver enormous shoulders which cannot otherwise be made to enter the pelvic brim. If the placenta is adherent to the uterine wall, its removal by hand is the only quick and safe method.

Abortion.—After membranes have been removed, the uterine cavity should be swabbed out with iodine it being an excellent antiseptic and hæmostatic.—PARVIN.

DEAFNESS FROM INTRA-NASAL DISEASE.

By JOHN A. THOMPSON, M.D.,

CINCINNATI, O.

All the scientific work done by physicians in their own field of labor is directed toward the prevention or relief of human suffering. Our physiological laboratories only fulfil the purpose of their creation when they investigate and teach the laws of normal being and show us how to avoid a disastrous conflict with them. Pathological investigations, including bacteriology, are meant to teach us the true nature of disease, that we may prevent or cure the abnormal processes revealed. We seek for knowledge only that we may apply it to the individual case. As the object of all this study is clinical, suggestions for physiological and pathological research must largely come from clinical observation. The experience of the physician in his daily rounds among the sick and suffering should show where we are lacking in knowledge. The practitioner should suggest the topics that the investigator may work out in the laboratory. I believe it a duty, where a physician encounters cases that cannot be explained by known physiological and pathological principles, to place these cases on record, hoping that some acuter mind may supply an explanation which will result in the prevention or cure of similar conditions in other patients.

Diseases of the ear are more intractable to treatment than those we encounter in any other department of medicine. Late cases of chronic catarrhal otitis media in either of its forms are regarded by experienced otologists as being almost hopeless by modern methods of treatment. From this hopelessness arises the constant suggestion of new procedures directed to the ear itself, in the hope of at least partially restoring the function which is so important to the happiness and success in life of the individual. A few observers, notably Swinburne, turning from the attempt to cure the already established condition, have sought to lessen the number of hopelessly deaf by seeking the cause and method of prevention. Swinburne examined the nose and throat carefully in a thousand cases which presented themselves at the Harlem Eye, Ear, and Throat Infirmary, complaining of deafness. Where deafness results from disease of the middle ear, his conclusions are that in ninety-five per cent. of all cases the primary lesion is in the nose or naso-pharynx. Just how disease in these organs produces chronic inflammation in the tympanic cavity has been a question of dispute. Some experienced writers claim it is due to the direct extension of inflammation by continuity of tissue. In structure the tympanum is only one of the accessory sinuses of the nose, though it differs entirely from that organ in function. Others have thought we could trace the resultant ear disease, secondary to obstructive lesions in the upper respiratory tract, to imperfect aeration of the middle ear. Still other authorities have thought that the interference with the circulation in the internal and middle ear by the inflammatory and neoplastic changes in the nose or naso-pharynx was the cause of the secondary disease. While the battle has been fierce and the flow of ink free in this wordy war, it is probable that all are right; that each method plays a part in the production of secondary diseases in the middle ear.

While I have seen many cases where the secondary deafness could be accounted for and the cure understood from the well-known relations of nasal and aural diseases, I have encountered others that are not susceptible of explanation by any of the known facts in rhinology or otology. I wish to report three of these cases, chosen because they are dissimilar in many of their features. They suggest that there is a relation not yet understood between the healthy condition of the nose and naso-pharynx, and the sense of hearing. In all of these cases there has been a serious and irremedial impairment of the organ of hearing, yet in all the ability to hear has been greatly increased by restoring the nose and throat to their normal condition.

Mrs. S——, aged thirty-one years, married when sixteen years old, has suffered from diseases of the generative organs since the birth of her first child. She is very nervous, weak, and anæmic. She suffered from pains in the chest, headache, cardiac palpitation, rapid pulse, and dyspepsia. These symptoms could not be relieved by ordinary constitutional treatment. She was referred to me by her physician, Dr. W. H. DeWitt, for the treatment of the upper air-passages, with the hope of relieving these intractable symptoms, which he believed were secondary to the local disorder.

The patient had marked hypertrophic rhinitis, with a deflected and thickened septum. The thickening was in the right nostril. There was also marked naso-pharyngeal catarrh. The right ear was deaf to all ordinary tests. She could not hear the watch on contact. She could not hear the conversational voice. She could hear loud voices only as an indistinct noise. She gave a history of this ear as follows: Seven years before, while suffering greatly from her uterine trouble, the ear became inflamed and was intensely painful for several days. The drum was finally perforated; the pain diminished with the free discharge of pus from the ear. She had had occasional attacks of acute suppuration in the middle ear from that time. Inspection of the ear showed a cicatricial drum membrane with evidence of old perforations. There was no suppuration at this time. The ossicles were firmly bound together by old inflammatory adhesions. The condition revealed by inspection was so bad that no attempt was made then or subsequently to improve the hearing by treatment of the ear. The hypertrophic rhinitis was treated by the usual method, and the spur on the septum was removed March 13, 1894. The headache and neuralgia of the chest, which the patient had supposed were all due to her uterine trouble, were entirely relieved within six months after this operation. The rapid pulse and cardiac palpitation yielded to the combined effect of the operation and heart tonics administered internally. The patient began to improve in health and strength and in a short time felt better, weighed more, and was better able to do her work than she had been for years. About ten months after the operation she discovered that hearing had returned to the supposed incurably deaf right ear. A careful test of this organ in April, 1895, shows that the patient is able to hear the conversational voice fairly well, and hears the watch, which was not heard on contact before the operation, two inches from the ear.

F. J. H——, aged eighteen, had scarlatina when he was thirteen years old. The scarlatina was complicated by purulent otitis media in both ears. The drum membrane and ossicles of the right ear were completely destroyed. In the left ear three-fourths of the drum membrane was destroyed and the ossicles remain bound together by cicatricial adhesions. With every cold the patient caught there would be suppuration from one or both ears. I saw him first in March, 1894. At that time he heard a conversational voice one foot, could not hear a watch on contact, and could not hear a whisper at all. There was no appreciable difference in the hearing powers of the two ears. He was about to lose his situation as clerk because of his inability to carry on a conversation with customers in the store.

Examination of the nose and throat showed hypertrophic rhinitis and a large spur on the septum in the left nostril. There was a complicating naso-pharyngeal catarrh. After treating the acute inflammation that was present when I saw him, for a few days, I removed the spur and cauterized the hypertrophied turbinated bodies so as to give him free breathing room through the nose. The left ear was suppurating when I first saw him, but this suppuration readily yielded to the dry treatment. The patient was under treatment

six weeks, and was dismissed with the ability to hear a whisper three feet and to distinguish ordinary conversation so readily that he still retains his position as clerk. December 1, 1894, he caught a severe cold, and with the resultant swelling and inflammation of the nose and throat his hearing became again seriously impaired. Ten days of local treatment cured this attack, and with the return of the nose to the normal condition the hearing distance for the whispered voice again became three feet for either ear.

Mrs. F. L. J——, aged thirty-five, has been deaf from childhood. I can get no distinct history of the cause of this deafness. She had repeated attacks of acute purulent otitis. In her earlier years she was treated by a number of good otologists, who succeeded in checking the suppuration, but did not prevent the total loss of hearing power in the right ear. She had been constantly under the care of a competent man for three years before I saw her. She had visited him once or twice a week all this time to have the left ear inflated by the Politzer method. This inflation gave temporary relief from the tinnitus aurium and improved the hearing temporarily. In spite of this treatment the deafness was progressive, and at the end of the three years she was worse than at the beginning of this period. Examination of the ears showed the right ear with only a perception of loud sounds. Inspection of the drum showed only a mass of cicatricial tissue, through which nothing could be seen to throw any light on the condition of the middle ear. The left ear showed a badly retracted drum membrane with cicatrices where old perforations had healed. Loud voice heard only one foot, watch not at all, in left ear. Examination of the nose showed a bad hypertrophic rhinitis, and in the right nostril, at the junction of the perpendicular plate of the ethmoid with the triangular cartilage, there was an enchondroma with a broad base nearly an inch in diameter and so thick that it completely filled the upper and anterior portion of the right nostril. As all known methods of direct treatment to the ear had failed to benefit the deafness, I decided to remove the enchondroma and to restore the lumen of the nostril by cauterization of the hypertrophied tissue in the turbinated bodies. The operation was made under chloroform October 11, 1894. I cut the nasal branch of the ophthalmic artery in the first incision for the removal of the tumor. This complicated very much an operation, always difficult to perform on account of the free bleeding hiding the field of operation. I removed the tumor as rapidly as possible and packed the nose with cotton saturated with McKenzie's styptic solution. Recovery was further complicated by an attack of follicular tonsillitis which began three days after the operation. The patient was already weakened from loss of blood and from the shock, so the attack of tonsillitis was unusually severe and prolonged. The immediate effect upon the hearing was of course disastrous. As soon as the patient was able to resume her visits to the office, the hypertrophied tissue in the turbinated bodies was destroyed by the galvano-cautery as rapidly as this could be done without exciting severe inflammation. The patient remained under treatment for four months and was dismissed with hearing distance for the watch, left ear, of nine inches. She hears the ordinary conversational voice with ease. She had never been able to hear a clock, which had been given her as a wedding present eight years before, until after this operation. On awakening one night she was very much alarmed at its ticking, though she was lying in bed across the room from the mantel on which the clock stood. Up to the present the improvement has continued, and I have no doubt the hearing will be better a year from now than it is to-day.

These three cases present few similar features. There was in all marked nasal obstruction from hypertrophy of the normal tissues and from the growth of abnormal structures. The condition of the ears in all was such as to offer no hope of cure by treatment of the ear itself. All were benefited so they could hear ordinary conversation, the best test of hearing power, by treatment of the nose.

In the first case reported the ear was never treated, either before or after the operation on the nose, yet as a result of this operation hearing is restored to an ear which to all appearances was hopelessly deaf.

In the third case the patient had been under the constant care of competent men from childhood to mature life. In spite of this care the hearing power was entirely lost in one ear and so far diminished in the other ear that common conversation could not be heard. Yet in this case the hearing power is restored to the ear by restoring the normal lumen of the nostrils. During the time she was my patient the ear received no treatment. It might be said the result in these cases was due to the fact that normal respiration and aeration of the middle ear through the Eustachian tube was restored. While this is a possible explanation, I do not believe it to be the true one. In the third case the Eustachian tube had been kept open by constant treatment, yet the deafness was increasing. The tube remaining open, no attention was paid to it while I was treating the nose, yet there was a remarkable gain in hearing power. It certainly will not apply to the second case, where in one ear there was no drum membrane at all and in the other ear only a remnant. The recurrence of the deafness months afterward when the nose became inflamed and swollen, and the prompt restoration of good hearing power by treatment of the nose, is an additional demonstration of the controlling influence that, in this case at least, the nose has on the power of hearing.

While I do not pretend to explain the influence which brought about the deafness or the cure in these cases, there is a practical conclusion to be drawn, upon which we can act, even if we do not understand thoroughly the theory or the principle on which our action is based.

This deduction is, that no case of supposed incurable deafness is really so unless the nose and naso pharynx have been examined and treated, if necessary, by a competent rhinologist.

ALKALINE INJECTIONS FOR THE TREATMENT OF GONORRHŒA.

By PHILIP JAISOHN, M.D.,

PATHOLOGIST TO THE GARFIELD MEMORIAL HOSPITAL, WASHINGTON, D. C.

The methods of treating gonorrhœa are almost as numerous as the individuals who are affected with this disease. There is no fixed rule governing the treatment of this common malady. For instance, the so-called "specific treatments" "work marvels" in one case, but fail in another. The books and journals are full of contributions and suggestions under the head of the treatment of gonorrhœa, according to the individual's experience as to what success he has obtained by a certain mode of treatment. However, all these various methods have one common object in view; that is, to arrest or destroy the growth of the germs which cause the inflammation. The majority of cases generally yield under these treatments in a more or less satisfactory manner, but as a rule the moderately severe cases never become entirely cured in less than four weeks' time.

It is needless to say how frequently we meet with those cases that have been supposed to be cured, which have developed into gleet, stricture, inflammation of the adjacent glands, etc. There is a new fact which has hitherto been unobserved, and which I think will be of interest to the medical profession. Before going further, it is necessary to understand the characteristics

of the germ which causes gonorrhœa (gonococcus), in order to describe the new fact more intelligently.

The gonococcus was discovered by Neisser in 1879, and cultivated by Baume in 1885. It is constantly present in virulent gonorrhœal discharges from the part in the interior of the pus-cells, or attached to the surface of the epithelial cells. Baume succeeded in cultivating it only in the blood-serum ; but no one has ever been able to make it grow in the ordinary peptonized bouillon, nutrient gelatine, or agar-agar. Recently, however, it has been successfully cultivated in the ordinary media, provided the media are rendered acid by adding a few drops of hydrochloric acid.

As a rule, bacteria do not grow well in acid media, whether they be of pathogenic or innocuous variety. Therefore the peculiarity of gonococcus is that it grows in acid, and not in alkaline media. For this reason gonococci flourish in the mucous membrane of the urethra or vagina, which are acid in reaction by the passage of urine and the glandular secretions. Knowing the fact that they do not grow in alkaline media suggests to us the idea of rendering the urethral or vaginal mucous membrane alkaline in the treatment of gonorrhœa. The obvious reason is to make the part as unfavorable as possible for gonococci to thrive in. I have treated six cases at different stages of the disease, and obtained the most satisfactory results by using alkaline antiseptic injections. At the same time, liberal doses of alkaline diuretics administered internally ; the object of which is not only to make the part alkaline by the local irrigations, but rendering the urine alkaline also. Of course, we must consider also the management of staphylococcus, which is always associated with gonococcus to produce pus, and aggravates inflammation in this form of urethritis. There is nothing which will destroy these pyogenic cocci more effectually than the solution of bichloride of mercury. For this purpose I use the mercurial solution at the strength of one to ten thousand, making this solution alkaline by adding liquor potassii at the proportion of one-half drachm to the ounce.

The injections should be given at least every four hours, and internally the following mixture is given :

℞. Sodii bicarbonatis..... ʒ j.
Spts. ætheris nitrosi..... f. ʒ ss.
Potassii citratis..... ʒ ij.
Infus. lini comp.....q.s. Ō j.
M. Sig. : Take a wineglassful every two or three hours.

My experience with this mode of treatment is limited, therefore I will not make more conclusive remarks in regard to its efficacy, but my faith concerning it is great. The chief merit of this method is that it hastens the recovery much quicker than any other procedure. In my own experience, four out of six cases became entirely cured within two weeks of the treatment, although in the beginning they were all severe types of gonorrhœa. The other two cases were of long standing, and they took longer to gain complete recovery ; but the gleety discharge diminished considerably after two or three irrigations, and disappeared altogether within three weeks.

Colica Pictonum.—

℞. Magnesii sulphat..... ʒ j.
Acid. sulphuric. dil..... f ʒ j.
Aquæ..... f ʒ iv.
M. Sig.: Give one tablespoonful three times a day, preceded by ten grains of iodide of potash.

—Brunton.

Rheumatism in Malta continues to be treated, in severe cases, by bee stings, a method which has preserved its reputation for a long time. The antidote is said to give great relief to sufferers, though on first hearing it does not recommend itself so well to the uninitiated.

GEOLOGY—A MEDICAL COLLATERAL.

By HARVEY B. BASHORE, M.D.,

WEST FAIRVIEW, PA.

The earth, or at least its upper layers, is beginning to have such an important place in the prevention of diseases and epidemics, that a study of geology must become of more or less value to the physician and the sanitarian ; the correct understanding of drainage and sewage disposal, of water and food supply, depend considerably on a definite knowledge of the earth's surface.

It is not long since, that through the labors of Schloessing, Müntz, and Warrington, we know the rôle of the nitrifying organisms in filth disposal ; summer and winter, nitrification goes on, and filth, changed into harmless compounds unfit for bacterial development, furnishes a nutrient for growing plants.

The study of wells, their quality, quantity, and pollution of their waters, depends notably upon the rock structure. The "strike" and the "dip" of a rock-bed are of vast importance in studying the drainage area and the water-supply. The "dip" of a stratum frequently determines whether or not a certain well is infected, and the character of an adjoining clay-bed may determine whether or not it forms an impassable barrier to a leaking cesspool or drain. The outcrop of an impermeable stratum will determine with surprising accuracy the depth to be drilled for a well, though far distant from the outcrop.

In artesian well-supply the water-bearing horizons are of the utmost importance, and geologists are now at work mapping them out in the eastern coastal plain ; by this means much useless labor has been saved, and districts which formerly drank polluted surface waters are now supplied with the pure water of a deep boring. The character of the water yielded in a certain place always depends upon the character of the rock-bed from which it is derived ; the hard and sparkling water of a limestone region—with its supposed calculi-forming properties—forms a marked contrast to the soft, palatable waters of a slate or sandstone region.

The location of certain strata may directly affect the health and comfort of large cities and wide-spread districts. For example, the Schuylkill, polluted by mine drainage and sewage, is partially, at least, purified by limestone strata crossing its course above Philadelphia ; the limestone changing the proto-sulphate of the mine drainage into oxide and sulphate of iron ; the oxide precipitating the organic matter thereby aids purification, and the sulphate is changed into the harmless calcium sulphate. The Susquehanna is likewise polluted, but the great limestone belt of Pennsylvania crosses the Susquehanna Valley below Harrisburg, and hence that city and all above suffer from polluted water.

The structure of a town site is at times of vast importance to the health of the dwellers thereon ; Bethlehem, Pa., suffered from an epidemic which was traced to its public water-supply, namely, a spring. How this became infected puzzled the physicians for some time, but at last the difficulty was explained. The town is built on silurian limestone, which almost always bears large underground streams and large water-bearing cavities ; the cesspools of the town, in certain places, pierced the water-bearing strata and infected the spring far away.

But it is in the last stages of geological history that effects were produced which had, perhaps, the most bearing on sanitary topics. The location of cities and highways, the drainage of large areas, the changing of old river courses, depend in a great measure on pleistocene formations. The great glacier and its concomitant phenomena, wherever they acted, literally changed the "face of nature."

In deep and narrow valleys, like that of the Susquehanna, their value and importance is more apparent, perhaps, than elsewhere, and anyone who has ever travelled northern regions will readily see how vastly civilization has been modified by the great glacier.

If pleistocene floods had not swept through our river valleys and deposited their layers of clay and gravel,[1] many cities would not stand where they do now, nor would railroads follow these natural highways.

Camille Flammarion tells us in his "Last Days of the World" some very fascinating facts about geological changes in the ages to come; how the very life-history and all nature of the globe is changed, simply by the increased permeability of the earth's strata; thereby, of course, leading to a diminution of water. While M. Flammarion's deductions are perhaps considerably exaggerated, we are, nevertheless, beginning to learn that geology is not all theory, but that it has some practical bearing on, at least, part of the world's life-history.

Progress of Medical Science.

The Treatment of Dysmenorrhœa. — Dr. Schwarze writes upon treatment of the forms of dysmenorrhœa which are unassociated with inflammatory disease of the uterus at its appendages, those due to anatomical changes and congenital malformation of the uterus, therefore that associated with pathological anteflexion, retroflexion in the virgin uterus, and the different forms of congenital deformity of the uterus. This class includes stenosis of the external and internal os and all forms of dysmenorrhœa in which no anatomical changes can be demonstrated. He believes the following drugs are of use: the preparations of iron, antipyrin, phenacetin, antifebrin, exalgin, and sodium salicylate. In some cases it may be necessary to administer codeine and opium, the dose being small. In young girls and women of apparent good health the Thure-Brandt's method of gymnastics of the entire body is frequently followed by marked benefit. It should particularly be applied for a week preceding each menstrual period. In well-developed and apparently healthy virgins, with severe dysmenorrhœa, the writer advises ext. viburnum prunifolium fl., a teaspoonful three times daily, for five to seven days before and during the menstrual period. Usually the Thure-Brandt gymnastics and the viburnum prunifolium treatment are combined. Massage of the uterus does good in those cases where there is an undeveloped or infantile uterus. It should not be employed in young girls. The introduction of a sound into the uterus just before the menstrual period, removing the pathological anteflexion and dilating the canal, is often followed by relief of symptoms. Rapid dilatation of the cervical canal a day before the period is the better method. Electricity applied to the uterus does good in many cases. The negative pole, an aluminium sound, is introduced into the uterine cavity, and the positive pole, a large, flat electrode, is placed upon the abdomen. A faradic current of from fifty to one hundred and fifty milliampères is employed. Finally, should there be no anatomical lesion and the menstrual period so very painful that life is made unhappy, oöphorectomy should be performed.—*University Medical Magazine.*

The Treatment of Vomiting.—A French physician recommends the following formulas, the first of which, according to Steffen, is useful in the vomiting of pregnancy: Distilled water, five ounces; tincture of iodine, twelve drops. A tablespoonful of this in half a glass of sweetened water is to be taken every two hours. The same author recommends the addition of a few milligrammes of morphine hydrochloride to each spoonful, or an ounce of the distilled water may be replaced by an ounce of cherry-laurel water. The *Centralblatt für die gesammte Therapie* recommends the two following formulas: 1. Chloroform, nine hundred grains; tincture of iodine, one hundred and twelve grains. Five drops of this are to be taken every night in a glass of Seltzer water. 2. Distilled water, three ounces and a quarter; cocaine hydrochloride, half a grain; antipyrine, fifteen grains. A teaspoonful may be taken every half hour. The following procedure, says the writer, in which three solutions are used, has often been employed successfully: 1. Alcohol, one hundred and fifty grains; menthol, eight grains; tincture of nux vomica, thirty grains. 2. Tincture of iodine, one hundred and fifty grains. 3. Saturated chloroform water, three ounces. Every half hour, or every fifteen minutes if necessary, the patient should take a dessertspoonful of the chloroform water, which may be diluted with iced Seltzer water, after having added ten drops of the first solution to it. If this is not sufficient, two drops of the tincture of iodine may be added to each spoonful. Finally, if it is necessary, from two to three drops of a 1-in 50 solution of morphine or cocaine may be added to these formulas. These two solutions are usually employed for subcutaneous injections. It is well to substitute occasionally for one of these medicaments from two to four drops of the ordinary solution of antipyrine for cutaneous injections, according to the following formula: Antipyrine, seventy-five grains; cocaine hydrochloride, two grains and a half; distilled water, a sufficient quantity to make ten cubic centimetres. If these different medications fail, says the writer, the physician may resort to the following therapeutic measure, which is very simple and has been successfully employed by M. Robin in serious cases: Apply a small blister to the pit of the stomach, also administer a small suppository containing a grain and a half of powdered crude opium and a sufficient quantity of cacao butter once or twice during the twenty-four hours. The vomiting is very often arrested, even if it is the serious vomiting of typhoid fever. Sometimes, also, inhalations of oxygen are useful.—*New York Medical Journal.*

Obliterative Arteritis in a Boy Fourteen Years of Age.—A case of this kind, occurring in a young boy, is reported in *The Lancet* by Dr. B. W. Bond. A boy, fourteen years of age, came to him suffering from a sharp attack of "shingles," extending around the left side of the chest and back. He was evidently in bad health, and on taking his left wrist to feel his pulse the doctor discovered that none could be felt. No pulse could be felt anywhere in the left upper extremity until the subclavian was reached. Here the beat was synchronous with that of the right subclavian, but much feebler. The radial and brachial arteries could be felt as cord-like bodies. On questioning the boy, he said that beyond occasionally having "pins and needles" in the left arm and fingers, he had felt no inconvenience whatever, and, in fact, he was unaware of the condition. He usually suffered from chilblains during the winter months, especially on the feet. The collateral circulation was evidently good, for beyond a slight blueness of the fingers, there was no other visible sign of deficient nutrition. The temperature of the fingers was practically the same on both sides, and there was no anæsthesia. As regards cause, there was no sign of cervical rib or pressure on vessels, the heart-sounds were normal, and no specific or rheumatic history could be obtained. There was no sign of congenital syphilis elsewhere. The pulse in the right radial was normal, and no undue thickening of arterial walls could be felt. The interest of the case lies in the early age of the patient. Dr. Bond has seen a similar condition at the age of twenty-three and twenty-four years, but believes it to be rarely seen in a patient as young as fourteen years.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 43, 45, & 47 East Tenth Street.

New York, September 7, 1895.

THE TREATMENT OF SPRAINS BY MASSAGE.

FROM a study of over twelve hundred recent cases of various kinds and degrees of sprain, Drs. Van Arsdale and Gallant (*The Medical News*) announce the following conclusions:

Massage is indicated in subcutaneous hemorrhage, traumatic joint inflammations, recent or of long standing, and other late forms of inflammation, such as that from rheumatism, etc.

Fractures at the ankle are not jeopardized by very early massage, but whether or not massage later on (during the first week) is harmful, all are not agreed. Immediate massage, on the contrary (if need be, under anæsthesia), permits of a better diagnosis, and in cases with great swelling hastens the union of fragments by removing the blood and exudation between them. If fracture is made out, the massage is not to be repeated. As to contra-indications, massage should never be applied in bacterial inflammations, *i.e.*, tuberculous, gonorrhœal, or pyæmic joints. The authors believe that massage of sprained joints will: 1. Prevent swelling, or rapidly disperse it if present. 2. Prevent pain, or quickly remove it when due, as it must be, to tension. 3. Prevent stiffness, or overcome it when already present from disuse. 4. Prevent the sense of weakness and restore the part to its original vigor and strength. 5. Reduce the time of treatment from weeks to a corresponding number of days. 6. Permit the immediate use of the injured member.

When it is remembered that the treatment of sprains by the older methods is often far from satisfactory, the good results obtained by massage in the hands of experts certainly claim attention. The general practitioner will do well, however, before entirely discarding these "older methods," to thoroughly acquaint himself with what joint massage really means.

Dr. Van Arsdale has described at some length his own method of procedure, and we cannot do better than transcribe his words:

"In treating a sprained ankle by massage it is convenient to have the patient lie at full length on a rather low table (from eighteen to twenty-four inches high) upon his back with his head on a pillow, or upon his abdomen, with the flexors of the leg relaxed. The limb should be bared to well above the knee, and no constricting garments should be permitted to interfere with the circulation in the thigh. Examination of the injured joint having been made, the circumference of the limb and the extent of motility noted, the entire foot and leg are next moistened with chloroform-oil uniformly applied by means of gentle rubbing over the entire surface. The gentle touch thus first brought to bear upon the parts has the advantage of reassuring the patient. In applying the emollient, care must be taken to arrive at a 'happy mean,' as too little will result in friction, which will irritate the skin and increase the discomfort of the patient, while an excess causes the hand to slip over the surface, and results in an unnecessary waste of strength, an early fatigue on the part of the *masseur*, without accomplishing the desired effect.

"Beginning well above the tender or swollen portions of the limb, gentle, systematic, upward strokes are carried well above the knee. These first strokes are made with the pulp of the fingers, both hands being used and held parallel with the leg. At first the sides of the leg are attacked, one with each hand; but soon more of the palmar surface of the fingers is brought into contact with the skin of the patient and gradually surrounds the whole circumference of the leg, each stroke being long and slow (not more than thirty to the minute). As the force of the pressure is gradually increased, the pulp of the thumb is brought into play, and the right hand supersedes the other in force and activity, until it will become necessary to grasp the lower part of the heel, or metatarsals, and make counter-traction in order to steady the limb and permit of a greater development of force.

"When the leg, by a change of color from blue to white, shows evidence of depletion of venous blood and lymph, the strokes may begin lower down and more directly over the seat of injury, always being carried upward with the pressure exercised by the fingers—delicate at first, but with ever-increasing intensity, with the thumb of one hand only, while the other hand steadies the foot in the most convenient position. The tissues, which were hard and resistant to the touch at first, soon become softer and more elastic, and with this the pain at first experienced by the patient grows gradually less and his confidence in the operation increases. From time to time, whenever the superficial veins of the leg that were first emptied appear engorged or swollen, it is considered imperative to continue the strokes upward above the knee, and repeat the massage of the upper leg in order to evacuate the newly imported supply of blood and lymph well into the vessels of the thigh, and, as it were, 'drive the fluids home.' In like manner the toes and the portions below the place of injury are visited and their tissues also are emptied of the stagnant fluids. The region around the ankle is now considerably smaller, paler, and softer than at first, and the thumb, keeping up the upward stroking all the time, and moving with an independent action against the fingers placed opposite to it on the limb, busies itself finding out the special points around the joint where more marked hardness and stiffness may be felt, and in diving down between the bony projections and tendon-sheaths, while it glides more lightly over the prominences and ridges of bone. The well-trained thumb is very quick at discovering the points of special sore-

ness, even without the help of the patient's subjective sensations, and will make them special points of attack. When fatigue is experienced, the hands are changed and the work carried on with the left.

"Toward the end of the *séance*, which must be indicated by the patient's sensations and condition, the strokes are made to grow gradually more gentle again, and, becoming longer, extend from the foot well up to the knee, more closely resembling those described by some authors as *effleurage*. This procedure always gives the patient a sensation of pleasure and relief, and when the *séance* is ended he should be entirely free from pain, at least for a time. If he is not, it is a sign that the massage has not been properly applied.

"Massage the limb twice daily, morning and afternoon, for half an hour at a time. After massage rest the joint for half an hour, and then permit the use of the limb in walking. Elevation of the leg between *séances* is always advisable. Moist warmth is useless."

A NEW METHOD OF EXAMINING THE RECTUM AND SIGMOID FLEXURE.

Dr. Howard A. Kelly announces a new method of examination and treatment of diseases of the rectum and sigmoid flexure. This method he has been using for eleven years, but has not perfected it until within the last two years. The details of his procedure are given in the *Annals of Surgery* for April, 1895.

The steps are briefly these: 1. Thorough evacuation of the bowels.

2. The patient is placed in a knee-breast posture, the elbows spread out at the sides, while the thighs are perpendicular.

3. A cylindrical speculum or proctoscope, provided with an obturator, is then introduced.

The buttocks are drawn apart and the blunt end of the obturator is laid on the anus, which is also coated with vaseline. The direction of introduction is downward and forward, and when the sphincter is well passed up under the sacral promontory. The moment the speculum clears the sphincter area, the obturator is withdrawn, then air rushes in and distends the bowel. This constitutes the fourth step in the procedure. Fifth, and last, is the inspection of the dilated bowel by light reflected from a head-mirror. Anæsthesia is usually unnecessary, since the specula are mostly of small calibre. They differ in length, the longest being 35 ctm., and this is called the sigmoidscope.

Dr. Kelly states that by means of this method of examination, he has plainly seen and sounded a stricture of the bowel 14 ctm. (five and a half inches) above the anus. He has also recently seen a polypus not more than 5 mm. in diameter, 10 ctm. (four inches) above the anus, and he has had occasion to examine cases diagnosed and treated for years as colitis, in which he found the rectum the seat of a chronic inflammatory trouble, limited either above or below the promontory by a perfectly sound mucosa.

A Fatal Name.—An Italian was recently killed in this city, during a quarrel, by a fellow-countryman bearing the deadly name of Morphini.

HIPPOPYRRHINE.

A venerable correspondent of the *Gazette des Hôpitaux* makes a suggestion regarding the use of the word vaccine and vaccinate. He recognizes, as so many others have done, the awkwardness of the term as applied to the inoculation of animals or men for the prevention of diseases other than smallpox. To use the word vaccinate in connection with diphtheria, rabies, or cholera, is manifestly an improper application of terms. Still we need something that will serve as an equivalent. In the case of the antitoxin injections for diphtheria, Dr. Badour, the writer in question, suggests the term, hippopyrrhinate, as an equivalent to the word vaccinate. The word is a combination of ἵππος, horse, and πυῤῥός, red. The last word has for its French equivalent the term *roux*, which is an ingenious compliment to Monsieur Roux, the pioneer in France of the anti-diphtheritic injection. Dr. Badour would therefore "hippopyrrhinate" children suffering from diphtheria rather than inoculate them with diphtheritic antitoxin. The French writer's idea is better than his suggestion. The average physician would be more embarrassed in attempting to use so clumsy a term than he would by the operation itself. There is, however, a distinct need for some general word which is the equivalent of vaccinate. The word immunize has been adopted largely, and fills to a considerable extent the need, but when a person has already been attacked with the disease such word is not applicable. We shall hope that some of the learned members of our profession, who are fond of word-making, will discover a term that will hit off the case aptly and euphoniously.

News of the Week.

The New Mexico Standard for Medical Colleges.—At a recent meeting of the New Mexico Board of Health it was resolved that examination will be required from all applicants to practise medicine in the territory who shall have been graduated after July 1, 1897, from any medical college not requiring preliminary examination of its matriculants, or equivalent evidence of satisfactory general education, and, for graduation, evidence of four years' study of medicine and four terms of lectures occurring in four separate years. Meanwhile the present standard of three years' study, three terms of lectures in three separate years, and preliminary examination of matriculants will be maintained for all applicants who have been graduated since July 1, 1890.

Hospitals and Horse-racing.—M. Lebaudy has sent to the French Hospital and Dispensary of London a donation of 25,000 francs, part of a prize won by a horse which he had entered at the Auteuil races.

The William F. Jenks Memorial Prize.—The author of the essay bearing the motto, "Vade mecum," which was designated as highly meritorious by the committee of award of this prize, was Dr. William Rienhoff, of Springfield, Mo. The essay was on the subject, "Infant Mortality during Labor, and its Prevention."

The American Academy of Railway Surgeons.—The second annual meeting of this society will be held in the banquet hall of the Auditorium Hotel, Chicago, on Wednesday, Thursday, and Friday, September 25, 26, and 27, 1895. The president of the Academy is Dr. C. K. Cole, of Helena, Mont., and the secretary Dr. Webb J. Kelly, of Galion, O.

The New York State Medical Licensing Examinations.—During the academic year from September, 1894, to June, 1895, inclusive, the total number of candidates coming up for examination before the State Licensing Board was 677. Of this number 507 were successful, and 170, or 25.1 per cent., were rejected. Six hundred and six of these candidates, of whom 161, or 26.5 per cent. were rejected, came before the regular board; 60, with 8 (13.3 per cent.) rejected, came before the homœopathic board; 11, with 1 (9.1 per cent.) rejected, came before the eclectic board. Of the candidates for the year, 83 came up for examination in September, 77 in November, 56 in January, 66 in April, 163 in May, and 232 in June.

The Cholera.—The London *Times* reported on August 29th that a man had died in one of the suburbs of that city, after a sickness which lasted sixty hours, and that a post-mortem examination indicated that his death was due to cholera. *The Lancet*, however, investigated the rumor and found that there was no proof whatever that the disease was Asiatic cholera, for a careful bacteriological examination failed to show the presence of Koch's spirilla. The reports of the disease in the East are, unfortunately, better founded. A despatch from Shanghai says that official reports show that there were forty thousand deaths from cholera in Pekin during August. Other parts of China, notably Nankin, and most of the large cities of Japan, are also suffering severely from the ravages of the disease. It is reported that cholera has been brought to Honolulu by a ship which touched there on her way from Hong Kong to San Francisco. The same ship, upon her arrival at the latter port, reported a clean bill of health. The customs officers have discovered, however, that during the ten days she lay there, there were in a cubby hole in the steerage three bodies of Chinamen who had died of cholera. The prevalence of cholera in Honolulu and in the Orient has created much anxiety on the Pacific coast. The Board of Health of Portland, Ore., is already adopting stringent quarantine measures, and it is thought that at no time have the cities in that part of the country been so seriously menaced as now. The disease has also been carried from Japanese ports to Vladivostock, in Siberia.

The Huxley Memorial.—According to a report in *Science*, the movement begun in England for the erection of a suitable memorial to Professor Huxley is taking form rapidly. A suggestion has been made that the monument be made international, and it is expected that, on the convening of the British committee, in October, this extension of the plan may be given formal approval.

A Ship's Crew with Beriberi.—The captain of a steamship, recently arrived here from Barbadoes, reports that when he left that port there was an American bark in the harbor whose captain and nearly all of the crew were suffering with beriberi. The bark had sailed from Aleppy, Madras, on May 16th, loaded with general merchandise bound for New York, and on the voyage nearly all of the crew and also the captain were stricken with the disease. They put into Barbadoes for medical assistance and fresh provisions.

An Epidemic of the Dancing Sickness broke out a few weeks ago among the school-children of Rehlingen, a village in Germany. During a violent thunder-storm that came on one day while the children were all in school, one of them, a girl twelve years of age, was suddenly seized with a general tremor, and soon after, jumping from her seat, began to dance wildly over the floor. Other girls immediately began to imitate her, and before long there were over thirty of the girls, and seven or eight of the boys, all hysterically dancing around the school-rooms. This was kept up for an hour or two, and was repeated the following day at about the same hour. The schools were then closed for three weeks in order to get the children into a normal state.

The Pilgrimage to Lourdes this year is the largest that has ever taken place. From fifteen thousand to twenty thousand ill and afflicted were received there every day. A great many reputed miracles have been reported; the cases are examined at Lourdes by a board of physicians, three of whom are English-speaking Protestants. A despatch in the *Sun* says that the reports of the pilgrimage were "in some features most appalling. The Orleans station in Paris was filled day and night by thousands of sufferers enduring indescribable agonies in the effort to reach the healing waters. Most of the time the air rang with shrieks of pain as the almost dying pilgrims were loaded or unloaded on the cars, which were packed to their utmost capacity. The scene one afternoon, when a special train from Germany, laden with six hundred invalids, many of them desperate cases, arrived for a change of cars, was enough to drive mad any spectator without the strongest nerve." The officials of the Orleans railway state that the returning trains have not nearly as many passengers requiring assistance as the departing trains.

Obituary Notes.—Dr. Edward Scott, of this city, a graduate of the College of Physicians and Surgeons, died in San Diego, on August 29th, of phthisis. He was twenty-eight years of age, and had gone to the Pacific coast three months ago in the hope of arresting the progress of the disease.—Dr. Thomas Henderson Chandler, Dean of the Harvard Dental School, died in Boston, on August 27th, at the age of seventy-one years.—Dr. Henry W. Rand, of Brooklyn, died at Sugar Hill, N. H., recently. He was born in Nova Scotia in 1851, and was graduated from the Bellevue Hospital Medical College in 1877. He was Lecturer on the Principles of Surgery at the Medical School of the Long Island Hospital. He left a wife and two children.

Mortality in New York State.—According to the State Board of Health bulletin, the average daily mortality in this State for July was 377, as against 293 for June. The average daily mortality during July in the past ten years was 370. More than one-quarter of the

deaths from all causes were from diarrhœal diseases, though the number from this cause was below the average for the past ten years. About fifty per cent. of the deaths from all causes were of children under the age of five years. Diphtheria caused less than three per cent. of the deaths, the mortality being below that of the corresponding month in 1894. Whooping-cough caused 143 deaths, measles 130, and scarlet fever but 32, all of them being in the maritime and Hudson Valley districts. There were no deaths from small-pox, and no cases of this disease were reported.

Cremation in the United States.—In a report made to the New England Cremation Society, it is stated that seventeen crematories have been established in this country during the past ten years. The number of bodies cremated in each of the ten years was as follows: In 1885, 36; in 1886, 119; in 1887, 125; in 1888, 199; in 1889, 262; in 1890, 362; in 1891, 464; in 1892, 576; in 1893, 677; in 1894, 876.

Public Baths in New York.—Mr. W. Tolman, Secretary of the Committee on Public Baths, recently reported to Mayor Strong that plans for the public bath-houses had been prepared and, after approval by the Health Department, adopted. The next step will be the selection of several sites for the bath-houses, and then the securing of the necessary appropriation, which it is hoped can be done in time to have one or more of the baths in operation by or before the beginning of next summer.

The Mortality in European Cities during 1894.—The death-rate of Berlin for 1894 was 17.2 in a thousand, that of London, 17.7; Brussels and Hamburg, 18.1; Amsterdam, 18.3; Copenhagen, 18.7; Turin, 18.8; Rome, 19.6; Glasgow, 20.0; Paris, 20.2; Manchester, 20.4; Vienna, 22.8; Liverpool, 23.8; Dublin, 24.7; St. Petersburg, 31.4; and Moscow, 34.1.

Mandelate of Antipyrin is a newly discovered combination which is said to have all the therapeutic properties of antipyrin, but without its injurious action upon the heart. Mandelic acid is obtained by the action of prussic acid and hydrochloric acid upon benzaldehyd.

The Pennsylvania and Maryland Medical Union Association held its eighteenth annual meeting at Columbia, Pa., on August 29th.

Medical Touts at Hot Springs.—The fight on the ropers and steerers goes merrily on. The doctors, almost to a man, are backing the authorities with money and influence, and we hope before long to be able to chronicle the fact that not one of these men will be left in our fair city.—*Hot Springs Medical Journal.*

Cimicifuga in Rheumatism.—Dr. David Hurd (*Medical Age*) is a firm believer in the efficiency of cimicifuga as a remedy for rheumatism of all kinds. He gives from four to six drops (presumably of the fluid extract) four times a day. The drug, like many others of its kind, possesses irritant properties which, in large amounts, produce vomiting and purging—a direct method of excretion possessed by the animal organism. In smaller doses it enters the circulation, and then it is only reasonable to suppose that the various excretory organs are stimulated to extra activity in throwing the offending substance out of the system. To this increased activity of the emunctories the improvement in rheumatic affections following the use of cimicifuga must doubtless be attributed.—*Pittsburg Medical Review.*

Etiology of General Paralysis.—At the recent French Congress of Alienists and Neurologists, M. Lagrange read a paper on "The Relation of Syphilis to General Paralysis of the Insane." Among 287 women in his hospital service, 6 had general paralysis, and of these only 1 was syphilitic. Of 250 men, 25 were paralytic, but only 2 syphilitic. One man, forty years of age, had contracted syphilis after he had had distinct symptoms of general paresis for some time.

Oxygen Treatment of Ulcers.—One of the most interesting demonstrations of the meeting was that by Dr. Stoker, of Dublin. It consisted in the application of oxygen gas to the treatment of chronic ulcers. The treatment consists in the incarceration of the affected part in a chamber charged with oxygen during several hours of each day. I recall one illustrative case of a large annular ulcer of the leg, which had defied all sorts of treatment in the London hospitals for years, and which was completely cured by this treatment in two months. One interesting test case was that of a woman with a very large ulcer on each leg, each practically like the other. The one was being subjected to the modern bichloride treatment, the other to the oxygen treatment. The former was free from all germ life, none being demonstrated by culture processes, while the latter abounded in practically all of the pathogenic variety, yet the latter ulcer was healing with twice the rapidity of the former. This fact would indicate that oxygen is not a germicide, and that the presence of pathogenic germs in an ulcer is not inimical to the process of repair. The paper, when published, will attract widespread attention, a fact for which the profession is in no sense indebted to the Council of the British Medical Association, which declined to give Dr. Stoker a place on the programme, but who, with true Irish grit, hired his own hall.—Dr. Charles A. L. Reed in the *Lancet-Clinic.*

One of the Early Woman Doctors.—A veracious writer in the Paris *Temps* tells a story of an English army surgeon, named Macleod, "a grave, skilful, wise, and reserved practitioner." His comrades sometimes rallied him on his sobriety and continence, but he replied only with a shrug of the shoulders. One day, in India, a lieutenant of his mess jokingly said that he lived like a young lady. Macleod jumped from his chair and slapped the officer in the face. A duel followed, and the lieutenant was shot. The surgeon then resigned and returned to England. Upon his death, some years later, it was found that the surgeon was a woman, and among her papers were found some showing that she was a member of one of the oldest families in Great Britain.

The Trade of Medicine.—A German paper gives an account of a danger menacing the welfare of doctors which has lately appeared in Munich in the shape of "medical corporations," advertised to furnish treatment at extremely low rates.

Reviews and Notices.

MANUEL DE SÉROTHÉRAPIE ANTI-DIPHTHÉRIQUE. Par le DR. M. FUNCK, Chef des Travaux Bactériologiques de l'Institut Sérothérapique de Bruxelles. Preface by PROFESSOR DESTRÉE. Brussels: H. Tanertin. 1895.

THIS may be said to be the first practical work of the kind on the methods of preparing antitoxin, the action of the serum, the technique of injection, etc. Besides this, in the one hundred and sixty pages are comprised an account of the evolution of serotherapy and the general results from it in diphtheria during 1894. The work is one of practical interest at the present time, and deals with the actual results of laboratory work and observation.

THE CELL. OUTLINES OF GENERAL ANATOMY AND PHYSIOLOGY. By DR. OSCAR HERTWIG, Professor Extraordinarius of Anatomy and Comparative Anatomy; Director of the II. Anatomical Institute of the University of Berlin. Translated by M. CAMPBELL and edited by HENRY JOHNSTONE CAMPBELL, M.D., Assistant Physician to the City of London Hospital for the Diseases of the Chest, and to the East London Hospital for Children. London: Swan Sonnenschein & Co. New York: Macmillan & Co. 1895.

THIS is an important addition to the literature of histological anatomy and physiology, and we are glad to find it translated into English for the use of those students who are unable to read the work in the original. The translation has been well done in the main, though it is a pity that the editor has apparently never heard of the word proton, proposed. we believe, by Wilder, as an equivalent of the German Anlage. Indeed, both author and editor might have improved their work considerably by a study of the American literature of the cell.

TRANSACTIONS OF THE NEW YORK STATE MEDICAL ASSOCIATION FOR THE YEAR 1894. Volume XI. Edited for the Association by E. D. FERGUSON, M.D., of Rensselaer County, N. Y. Published by the Association.

THIS handsomely printed volume, of some seven hundred and fifty pages, contains a number of interesting papers on a great variety of subjects.

A SUMMARY OF THE VITAL STATISTICS OF THE NEW ENGLAND STATES FOR THE YEAR 1892. Boston: Damrell & Upham.

THIS is a concise statement of the marriages, divorces, births, and deaths in the six New England States for 1892. It has been compiled under the direction of the Secretaries of the Boards of Health of these States, and is an important contribution to statistical literature.

ANNUAL REPORT OF THE SUPERVISING SURGEON-GENERAL OF THE MARINE HOSPITAL SERVICE OF THE UNITED STATES FOR THE YEAR 1893. In Two Volumes. Washington: Government Printing Office. 1895.

THESE volumes contain the usual reports of the Marine Hospital surgeons and inspectors on duty in this country and abroad. They are an evidence of the good work done by the officers of this service under the able and energetic direction of Dr. Wyman. In looking over these reports, however, one is constantly reminded that the work done belongs in no sense to the Treasury Department, but should be done by officers of a National Health Department.

ENCYCLOPAEDIE DER THERAPIE. Herausgegeben von OSCAR LIEBREICH, Dr. Med. Geheimer Medicinalrath, o.ö. Professor der Heilmittellehre an der Friedrich-Wilhelms-Universität, unter Mitwirkung von MARTIN MENDELSOHN, Dr. Med., Privatdocent der Inneren Medicin an der Friedrich-Wilhelms-Universität, und ARTHUR WÜRZBURG, Dr. Med. Kgl. Sanitätsrath, Bibliothekar im Kaiserlichen Gesundheitsamte. Erster Band, erste Abtheilung. Berlin: August Hirschwald. 1895.

THIS is the first part of the first volume of what promises to be a work of great merit and utility. It is not strictly an encyclopædia of therapeutics, for a number of subjects treated, as, for example, amyloid degeneration, are as yet beyond the reach of treatment. It is perhaps rather an encyclopædic medical dictionary with special emphasis upon the therapeutic titles. Many of the leading clinicians of Germany, in addition to those specially designated as editors, are contributors to the work. Among the more important subjects dealt with in this part are: Abscess, Absorption, Acids, Alcohol, Diseases of Old Age (Alterskrankheiten) Anæsthesia, Antidotes, Antimony, Antiphlogosis, Antipyretics, Antisepsis and Asepsis, Arsenic, Asthma, Medication (Arzneianwendung), and Atropine. One of the titles, written by Ewald, is on Achylia Gastrica, the term proposed by Einhorn for a condition in which there is no secretion of the gastric juice. This and many other articles show that the work is fully up to date. The completion of the work is promised within the next two years.

THE LONDON HOMŒOPATHIC HOSPITAL REPORTS. Edited by GEORGE BURFORD, M.B., C. KNOX SHAW, and BYRES MOIR, M.D. Vol. IV. London: Homœopathic Hospital. 1894.

THIS volume contains a number of papers on various subjects by the leading homœopathic practitioners of London.

THE AMERICAN ACADEMY OF RAILWAY SURGEONS. Official Report of the First Meeting. Edited by R. HARVEY REED, M.D. Chicago: American Medical Press Association. 1895.

THIS volume of transactions contains the history of the Evolution of the American Academy of Railway Surgeons as well as the report of its first meeting in Chicago, in November, 1894.

THE RETROSPECT OF MEDICINE. A Half-yearly Journal, Containing a Retrospective View of Every Discovery and Practical Improvement in the Medical Sciences. Edited by JAMES BRAITHWAITE, M.D., Obstetric Physician and Surgeon to the Leeds General Infirmary, etc. Vol. CXI. London: Simpkin, Marshall, Hamilton, Kent & Co. 1895.

BRAITHWAITE'S Retrospect appears with its accustomed regularity, and contains the usual amount of abstracts from periodical literature. This excellent work holds its own well in competition with its younger rivals.

SKIASCOPY AND ITS PRACTICAL APPLICATION TO THE STUDY OF REFRACTION. By EDWARD JACKSON, A.M., M.D., Professor of Diseases of the Eye in the Philadelphia Polyclinic and College for Graduates in Medicine; Surgeon to Wills Eye Hospital, etc. With twenty-six Illustrations. Philadelphia: The Edwards & Docker Co. 1895.

THE object of this book is to urge a more general adoption of skiascopy in the examination for ametropia. The method is one which is but little employed by ophthalmologists, but the author believes that this neglect is the examiner's loss. The description of the test is clearly expressed, and the author writes with all the authority and the enthusiasm of an expert. Young ophthalmologists cannot afford to gnore skiascopy, and they can nowhere find it better explained than in this little work.

THE EYE IN ITS RELATION TO HEALTH. By CHALMER PRENTICE, M.D. Chicago: A. C. McClurg & Co. 1895.

THE author of this curious book was evidently prepared to encounter adverse criticism, for he begins with the definition of a critic and recounts his necessary qualifications. We confess we have been unable to verify the facts of astounding cures of organic diseases by the fitting of glasses, as recounted by the author, which run counter to all medical experience from the days of Hippocrates up to that of Prentice. Among the cases which the author asserts that he has cured by eye-glasses are many of pulmonary tuberculosis, diabetes mellitus, ovaritis, "female weakness," Bright's disease, prostatitis, insanity, cirrhosis of the liver, sterility, rheumatism, and uric-acid diathesis.

O QUARTO CENTENARIO DA FEBRE AMARELLA. Pelo DR. CARLOS SEIDL, Director do Hospital de S. Sebastião. Rio de Janeiro: Besnard Frères. 1895.

THIS is a brief monograph written to commemorate, but not to celebrate, the quadri-centennial of the first appearance among the Europeans, companions of Columbus, of yellow fever. This occurred on March 24, 1495.

CHART OF THE SYMPATHETIC NERVOUS SYSTEM. By BYRON ROBINSON, M.D. Chicago: E. H. Colgrove & Co. 1895.

THIS is a drawing, life-size, of the sympathetic nerve, made from dissections. It gives one a very clear idea of this important part of the nervous system.

OFTALMOLOGIA CLÍNICA. Por el DR. ENRIQUE LOPEZ. Segunda Serie. Habana: Imprenta del Avisador Comercial. 1895.

THIS is a study of 1,000 cases of affections of the eye conducted on the same plan as an analysis of a former series of 1,000 cases published by Dr. Lopez five years ago. This volume is illustrated by sixty-seven wood-cuts. The work is a valuable contribution to ophthalmological literature.

A COMPLETE CASE RECORDER IN GENERAL MEDICINE AND GYNECOLOGY, for the Use of Physicians, Students, Dispensaries, and Hospitals. By S. B. LYON, M.D. Chicago: A. L. Koursh & Co. 1895.

THESE blanks are intended to assist the student in hospital or the practising physician in keeping an accurate record of his cases. They seem to be well adapted to this purpose.

STUDIER OVER ÆTIOLOGIEN OG PATHOLOGIEN AF ILEUS. Af JOHAN NICOLAYSEN. Kristiania: Det Steenske Bogtrykkeri. 1895.

THIS is an interesting monograph, illustrated by two colored plates, based upon a careful study of thirty cases of ileus. Fourteen were due to internal obstruction, sixteen to strangulation of the gut from external causes.

ANUARIO DE LA CLÍNICA PRIVADA del DR. FARGAS. Barcelona. 1895.

THIS is a report of the gynecological cases occurring in the private practice of Dr. Fargas during the course of a year. The subjects treated are surgical intervention in uterine myomata, torsion of the pedicle in ovarian tumor, anæsthesia, aseptic methods employed by the author, vaginal applications, and a description of an operating-table.

LA MEDICACIÓN ANTITÉRMICA EN LOS PROCESOS FEBRILES AGUDOS. Por J. QUERALTO, Profesor Auxiliar de Clínicas en la Facultad de Medicina de Barcelona, etc. Barcelona: Francisco Martinez. 1895.

THIS excellent monograph on antipyretic medication in acute febrile conditions obtained the prize of the Royal Academy of Medicine and Surgery of Barcelona, in 1892. The author's conclusions are, in general, that fever calls for no treatment other than that directed against the causal condition, except when it rises to a dangerous height. In such case the antipyretic that is of the most value is the cold bath; alcohol in moderate doses is also very beneficial.

Clinical Department.

CASES OF BRAIN TUMOR.[1]

BY GEORGE J. PRESTON, M.D.,

PROFESSOR OF PHYSIOLOGY AND DISEASES OF THE NERVOUS SYSTEM, COLLEGE OF PHYSICIANS AND SURGEONS, BALTIMORE, MD.

SINCE the last meeting of this Society, several cases of tumor of the brain have come under my notice, among which the following are perhaps worthy of record:

CASE I.—Samuel F——, colored, aged thirteen. Family history negative, except that the father gives a suspicious history of syphilis. The boy's personal history was good; he has had the usual diseases of childhood, but has been fairly healthy. In April, 1893, he had a convulsion, which was attributed to undigested food. A few weeks after this he had another convulsive attack, and since has had two or three attacks a week. The attacks are general, attended by total loss of consciousness. Just before the attack comes on he holds his arms out in front of his body. When first seen at the dispensary the case was regarded as one of idiopathic epilepsy, and the attacks were very much lessened in frequency by the bromides. After he had been some months under treatment he suddenly developed diplopia. An examination of his eyes, kindly made for me at this time (March 14, 1894) by Dr. Harry Friedenwald, showed paralysis of the right external rectus and intense neuro-retinitis of both eyes. V.—R. E. $\frac{6}{\infty}$, V.— L. E., reduced to counting fingers at 4 to 5 feet. There was also left lateral achromatopsia. At the next examination, a week later, central vision was the same; but there was now left lateral hemiopia, complete in the upper half of the field, and partial in the lower. The part preserved on the hemiopic side was still further reduced by March 16th, ten days later. The boy was admitted into the hospital June 16, 1894, when the following notes were made: Organs of circulation, digestion, respiration normal. Urine shows no trace of albumin or sugar. Great loss of strength and general emaciation. Is barely able to stand, and cannot walk without assistance. There seems to be some tendency to fall backward. Both superficial and deep reflexes absent. Complains of intense headache, and the head seems very sensitive to percussion. Tactile and pain sense greatly impaired. By this time the paralysis of the right external rectus had entirely disappeared. Hearing was greatly impaired by April 3d, and when admitted into hospital the boy was completely blind and deaf. The optic nerves now showed post-neuritic atrophy. The boy's strength gradually failed, and death took place on July 22d.

The autopsy revealed a tumor measuring something like 6 × 6 ctm., situated in the right temporo-sphenoidal lobe. The growth apparently started from the inner surface of the dura mater, and the bones of the right middle fossa were eroded by the pressure. The whole of the right temporo-sphenoidal lobe was softened and disintegrated, and the softening also involved the right occipital lobe. The right cuneus was softened in its centre, but the gray matter was not invaded. The only part of the cortex involved was the temporal lobe. The ventricles were full of fluid. Other organs normal. Microscopic examination of the tumor showed it to be a sarcoma.

CASE II.—Georgianna C——, colored, aged thirty-nine. Family history negative, except that a brother had epilepsy. Personal history negative. Examination of chest showed pulmonary tuberculosis. Heart normal. No albumin or sugar in urine. Reflexes, superficial and deep, normal. Patient states that she has had intense, unintermittent pain in the head, and locates the pain about the junction of the lamboid and sagittal sutures. There is marked tenderness on percussion at this point. According to the statements of patient this pain began five or six weeks prior to entering the hospital. Mental power is distinctly impaired; there are no delusions, but she answers questions in a vague, uncertain way, and her talk is rambling. Patient has had epileptiform attacks for some months past, and says she can tell when the attacks are coming on by certain peculiar feelings in her arms, particularly the right. Examination of the eyes shows double optic neuritis, with congestion and tortuous veins. The right eye has many retinal hemorrhages.

Death occurred from pulmonary tuberculosis, and the autopsy revealed a circular, firm tumor, fungoid in appearance, measuring 2 to 3 ctm. in diameter, and attached to the under surface of the dura. The tumor imbedded itself in the superior occipital convolution of the right side, making a cavity about the size of a partridge egg. Microscopic examination of the tumor showed it to be a papilloma. The ventricles were full of fluid, the brain otherwise normal. The interest of this case lies in the marked symptoms, head pain and tenderness on percussion and optic neuritis, caused by a tumor of such small size and located in such a comparatively unimportant part of the brain.

CASE III.—Henry J——, colored, aged thirty-five, was brought into the hospital in a convulsion. Gave a history of having had fits before, but it was impossible to fix the date of onset. Organs of circulation, respiration, and digestion were normal. Examination of the urine showed albumin and casts. There was no paraly-

[1] Read before the Twenty-first Annual Meeting of the American Neurological Association, Boston, June 5th.

sis of motion or sensation, and the reflexes, superficial and deep, were present. Ophthalmic examination showed congestion of eye ground, but the condition of the patient was such that no thorough examination could be made. After a few days the patient's general condition improved somewhat, and he complained of intense headache, unintermittent in character, and not confined to any particular part of the head. At this time a peculiar tremor developed; starting in the left arm, it gradually involved the shoulder and head of the same side. In a few days the tremor became general, involving the whole body, and a rather active delirium set in. Patient would answer questions, but in an irrational way; there was no deafness. He finally became maniacal, and had to be tied in bed. For a few days his delirium took a religious turn, going to heaven, conversing with the Lord, etc. He then took a turn at swearing, and for several days kept this up constantly. The patient became gradually weaker, and died November 15th, or about two weeks after admission to the hospital.

The autopsy showed a tumor growing apparently from the dura, involving the posterior portion of the left temporo-sphenoidal lobe, the occipital lobe of left side, and the left lateral lobe of the cerebellum. The growth destroyed the posterior half of the second and third convolutions of the temporal lobe, but did not touch the first convolution. It will be remembered that there was no discoverable impairment of hearing. The occipital lobe was also involved, most of the angular and supra-marginal gyri being compressed. The tumor encroached slightly on the under surface of the left lateral lobe of the cerebellum. It is to be regretted that the condition of the patient was such that no accurate examination of the eyes could be made. The tumor was a sarcoma. The liver and kidneys were cirrhotic, and spleen small and cirrhotic.

Case I. was the only one in which operation was suggested, and the father of the child refused permission. In the other two cases, although a diagnosis of brain-tumor was made, definite localization was impossible.

THE COEXISTENCE OF ERUPTIVE FEVERS.

By A. A. HIMOWICH, M.Sc., M.D.,

NEW YORK.

VISITING PHYSICIAN, BETH ISRAEL HOSPITAL.

John Hunter[1] announced his doctrine on this subject in the following language:

"As I reckon every operation in the body an action, whether universal or partial, it appears to me beyond a doubt that no two actions can take place in the same constitution, nor in the same part at one and the same time; the operations of the body are similar in this respect to actions or motions in common matter.

"It naturally results from this principle that no two different fevers can exist in the same constitution, nor two local diseases in the same part, at the same time. . . . In two eruptive diseases, when both are necessarily the consequence of fever, and when both naturally appear after the fever, nearly at the same distance of time, it would be impossible for the two to have their respective eruptions, even in different parts, because it is impossible that the two preceding fevers should be coexistent."

Charles Murchison,[2] commenting on Hunter's views, very justly remarks that this doctrine is at variance with clinical experience. At present there are very few physicians who have not met cases in which the coexistence of two fevers was plainly manifest, but the coexistence of eruptive fevers is indeed of rare occurrence. We very often meet cases of scarlet fever and diphtheria, measles and diphtheria, but we do not often meet typhus or typhoid fever together with scarlatina, nor scarlatina together with measles. Because of the comparative rarity of such coexistences I consider the following cases worthy of record:

Case I.—S. S——, female, about three years of age, was taken sick with an unusually high fever. As no cause could be found to account for the high temperature, I deferred diagnosis until further development and treated this symptom by frequently sponging the body with alcohol and water. Two days later there appeared the well-known eruption of varicella, but this did not in the least diminish the severity of the fever.

As I had never before seen such a peculiar case of varicella, I watched my little patient with extreme interest. Next day my attention was called by the mother to the patient's throat, as she observed some difficulty in swallowing. The throat was typical of scarlet fever; an examination of the body revealed the scarlet eruption. The case proved to be a very severe scarlatina.

There were two more girls in the family. One older, who had already suffered from this disease, and one younger. The latter was not isolated at the beginning, and when the true nature of the disease was ascertained I considered it too late for isolation.

I must confess that there was also the desire to see how her younger sister would be affected. The result was that this child went through the same experience as her sister, viz., high temperature, varicella, and scarlet fever. Both suffered subsequently from nephritis, and both recovered.

Case II.—R. S——, female, four years of age, was brought to my office for treatment. Her mother made the diagnosis of varicella, but she thought the child was also sick otherwise. The diagnosis was correct, but as the fever was higher than in an ordinary case of varicella, and the general appearance bad, I ordered the child to be put to bed and fed on milk alone. Next day I found the typical eruption of scarlatina on the child's body and face; the throat was also one of scarlet fever. The disease in this case ran a much milder course than in the two previous cases.

Case III.—S. K——, female, about three and one-half years of age, was brought to my office for general distemper. The mother gave me the following history: The child had a red eruption on the body first, then on the face and extremities; but no other symptoms were observed. At night she would have some fever, which would disappear in the morning. The child was playing during the day with other childeren of the same tenement, and there was nothing to indicate that medical advice was necessary. The eruption was all gone, but the child's general condition became very bad. From the history, it seemed evident that the patient was suffering from a mild attack of scarlet fever. The examination strengthened this supposition. The child's body was in the desquamative stage, and there was albumin in the urine. On further questioning I learned that there were other children suffering from scarlet fever in the same house about the same time that this child had the eruption. The child had bronchitis, not of a severe form; surely not enough to account for the general debility and malaise. Considering the nephritis mostly responsible for the trouble, I began to treat the kidneys, with the result that the amount of albumin was diminished considerably. The fever increased steadily, and with increase of fever the pulmonary symptoms became worse. This led me to believe that the fever was due to the development of a broncho-pneumonia. The mother noticed that the child's eyelids were red and heavy, and there was a great deal of sneezing and coryza. The same night the whole face and body were covered with a red eruption, while the severity of the fever abated. When I saw the child in the morning I was struck by

[1] John Hunter's Works, Palmer's Edition, vol. iii., p. 4.
[2] Murchison on Fevers, Second Edition.

the peculiarity of the rash. There was surely measles, but besides measles there was also the distinct eruption of scarlatina. Both eruptions coexistent in the same child at the same time! The scarlatina was probably a reinfection from the previous attack.

Dr. Francis Huber also saw the case in my absence. When I was informed of the fact I saw Dr. Huber, and he told me that he could plainly distinguish the eruptions of both measles and scarlatina.

These cases show that eruptive fevers may be coexistent, not only varicella and scarlet fever, but also measles and scarlatina. This coexistence is probably of greater frequency than is generally supposed, but the symptoms of one fever mask the other so that it is rarely recognized and very often not even suspected.

That one attack of scarlatina does not always immunize the individual from another attack of the same disease, and that they may follow each other in rapid succession, undisturbed by other pathological changes in the same system, is clearly shown in the last case here reported.

136 Henry Street.

TREATMENT OF TYPHOID FEVER.

By WILLIAM E. PUTNAM, M.D.,

WHITING, IND.

I believe that typhoid fever, like diphtheria, is first a local trouble and then becomes systemic. I first empty the bowel and unload the portal circulation, using calomel or cascara sagrada, or any other efficient laxative, so that the bowel is well emptied. At my first visit I put the patient in possession of the largest and best room in the house.

Usually all carpets, rugs, and curtains are taken up. During the last two years I have not used aconite or fever remedy of any kind internally. I order first a soap-and-water bath, going over the body a little at a time and covering all parts not under the brush. Then I have the nurse give an alcoholic rub. This is always followed by a fall in temperature of from one to two degrees and one or two hours' sleep. To lower a fever of 104° F., I have the nurse wet the whole surface of the body with alcohol, wait five minutes and go over the patient again; then take the temperature and, if not low enough, go over patient once more, but not to exceed three times, with the alcohol. Internally I used for several years turpentine in emulsion, after an excellent article I read in the Medical Record. Then I used salol with good results. For the last two years, I have used sulphocarbolate of zinc in two-grain tablets. Dose, four grains every two to four hours. I have lately treated about twenty cases with sulphocarbolate of zinc, depending almost entirely on that one drug. A number of times, when the temperature would jump up two or three degrees, I have doubled the dose of my sulphocarbolate of zinc, and it acted on the typhoid poison in the canal in such an effective manner as to bring the fever down two or three degrees. I claim in all cases where the bowels are open that four-grain doses of sulphocarbolate of zinc will lower the temperature. In private practice, when the patient eats forbidden fruit, as we know they oftimes do, I never hesitate to go after it and chase it down through the canal with half a grain of mild chloride of mercury or cascara sagrada tablets.

Nitrate of strychnia, grain $\frac{1}{30}$, every four hours all the way through, will give your patient comfort and help his lungs to pump more good air. This drug is best given in tablet triturates.

During convalescence I give the old standby—quinine, strychnia, and iron. Since 1885 I have not lost one case of typhoid where I was called during the first ten days of the disease, and I have had as high as twenty-three cases of typhoid under treatment at the same time.

Society Reports.

THE BRITISH MEDICAL ASSOCIATION.

Sixty-third Annual Meeting, held in London, July 30 and 31, and August 1 and 2, 1895.

(Specially Reported for the Medical Record.)

SECTION OF SURGERY.

First Day, Wednesday, July 31st.

Address of the Chairman.—Sir William MacCormac took as the subject of his address "Some Points of Interest in Connection with the Surgery of War." He said that a study of the effects of the new small-bore rifle-bullets and the injuries that they inflicted was one that it was impossible to over-estimate. It was to be regretted that in the British army the principal medical officer in the field was not given that influence in the councils of the general commanding which was his due. The disposal of the enormous number of wounded that was sure to collect after a general action in the future was a question that would have to be reckoned with. The speaker showed specimens obtained in the war of 1870–71, exhibiting the shattering effect on bones of the large bullets then in use. There was a strong family likeness between the new rifles adopted by all the European powers. The bore was, upon the average, less than one-third of an inch, the charge of powder varied from 215 to 225 grains, the bullet resembled a lead-pencil, and its length was about four times its diameter. It described twenty-five revolutions in a second, had an initial velocity of two thousand feet per second, and an effective range of about two miles. Hitherto nine-tenths of the wounded in modern war were injured by rifle-bullets. Many experiments had been conducted with a view to ascertain the nature of the injuries that would probably be met with in future wars. Leaden vessels and pipes filled with jelly had been fired at, at short ranges, and the results noted. The distortion and explosive effects were enormous. Large rents were made, and the walls of the vessels bulged out in various directions. The explosive effect seemed to occur after the bullet had traversed the vessel; for the displaced wall could, in many cases, be pushed back, showing the cleanly cut round hole of exit.

The German War Ministry, with its characteristic practical foresight, had instituted and carried out a series of elaborate experiments in order that German military surgeons might be prepared, as far as possible, for the nature of the injuries that they might be called upon to treat. In the museum in Berlin there were now upward of one thousand specimens, the result of these experiments. Most elaborate precautions were taken, which the speaker detailed, so that the bodies of men and animals fired at should be, as far as possible, under the conditions in which they would be struck in real warfare. In examining the wounds frozen sections were made, or the track of the bullet injected with fusible metal. At a range of two thousand yards the bullet traversed the skull, thorax, or abdomen. The liver was the organ that suffered most damage, being, in some cases, almost pulped. The intestines were perforated by multiple wounds, from three to eight in number. The effects of a bullet, fired at a range of fifty metres, on a full skull were appalling, its walls being shattered fearfully. On an empty skull, beyond the two perforations, little damage was inflicted. Using reduced charges at a short range, the effects were proportionately less severe. When the shaft of one of the long bones, such as the femur, was struck, great damage was inflicted, the bone being shattered for a distance of five or six inches. When the cancellous tissue at the end of a long bone was struck,

much less damage was caused beyond the perforation. The conclusion to be drawn from these experiments on the long bones, and from the specimens exhibited, was that the damage done was very great up to ranges of two thousand yards or even more. The openings of entrance and of exit were both small, but great damage was done in between, as in the case of an ankle-joint, which was quite shattered. The new bullet was often found to be unchanged in appearance even after penetrating cancellous bone. After richochetting, the bullet was extremely dangerous, as its hard covering was liable to be torn and the sharp edges cut through arteries and other soft parts. In 4.5 per cent. of the bullets found after inflicting a wound, there was deformity of the projectile. As regards the danger of hemorrhage, primary bleeding was much more likely to occur in wounds from the new bullet than from the older, while secondary hemorrhage would be less frequent. It was well known that in the field wounds of the large arteries are generally fatal, for the patient dies before help can reach him. It was, therefore, greatly to the credit of the Japanese that in the late war with China they saved two such cases, one of wound of the brachial artery, the other of the femoral. This showed how closely their bearer companies must have attended on the troops engaged.

It was noteworthy that large vessels were frequently only partially divided by the new bullet, and this, to some extent, explained the greater liability to primary hemorrhage.

As Volkmann had observed, injuries to bones caused by gunshot are less serious and heal much better than injuries of the like extent inflicted by other forms of violence. The experience of the German-Russian surgeons von Bergmann and Reyher in Europe and Asia respectively, during the Russo-Turkish War, was remarkable. They recorded most successful results of conservative treatment in cases of wounds of the knee-joint.

In future, conservatism must be the rule in the treatment of gunshot wounds of the bones. Direct wounds of the lung by the new bullets were simple, and unless a large vessel or bronchus were wounded almost trivial. Splinters of bone were seldom carried in. When, however, the bullet glanced off some external object, the injuries were serious. Otherwise the elastic air-containing substance of the lung suffered scarcely any harm beyond the small track of the bullet.

Excluding suicidal cases, the mortality in lung wounds recorded was only 12.5 per cent., and all these cases succumbed to injury of large vessels or bronchi.

Injuries of the skull are very serious. In 1870–71 ten per cent. of the wounded were injured in the skull, but in not all of these was it penetrated. In future, probably, the skull would be seriously fractured or fissured whenever it was touched by a bullet.

Wounds of the abdomen will probably be invariably fatal, unless an early laparotomy can be performed. This affords the only hope of recovery, but it is probable that in the field in the confusion and strain attending a general action, with hundreds of wounded needing help, the surgeon will be unable to afford the time and care needed for its performance. Skilled assistance will also perhaps be scarce.

It is to be expected that the next great war will be far more destructive to life than former wars of modern times, but the recoveries among the cases treated will probably be more numerous. Bullets will seldom lodge in the body, and should one do so, it should be left alone and not searched for. The probe will be less used and, as Fischer has said, the surgeon at the dressing station must use his eye more than his hand.

The address was illustrated by numerous lantern slides and preparations lent by Professor Hueter, of Greifswald, and by others.

Rhinoplasty.—Surgeon-Major Keegan then read a paper on "Rhinoplasty in India." His experience had been chiefly among young and healthy patients, principally women who had been mutilated by jealous husbands or others. The operation which he usually practised was that described in Treves's "Operative Surgery." He removed a flap of skin from the nasal bones, and having reversed it so that the epidermal surface was inward, used it as a lining for the newly formed nares in order to prevent subsequent contraction. A flap brought down from the forehead was used to cover the surface thus denuded and to complete the nose. In dividing the root of the flap later on, he was careful to cut a wedge-shaped piece out of it, in order to preserve the shape of the bridge of the nose. Lantern photographs of several women and one man, showing their condition before and after operation, were projected on the screen. The results in all cases appeared to be excellent. There was no discussion on this paper.

Fracture of the Femur.—Sir William Stokes, of Dublin, then read a paper on the "Diagnosis and Treatment of Fractures of the Upper Third of the Femur." He said the subject was perhaps not so interesting as the more modern developments of surgery, such as operations on the brain, the abdomen, etc. It was good, however, to look back from time to time and revalue the conclusions that had been arrived at. Some surgeons thought that the amount of attention that was devoted to the diagnosis of certain injuries in and about the joints was excessive. He could not agree with this view. He held that as long as anything was unknown, no amount of attention was excessive that would help to throw light upon it. At present inquirers into this subject were impeded by a dense jungle of conflicting symptoms. He contrasted these, and referred to the fact that in the repair of some cases of injuries of the upper end of the femur there was exuberant bone formation, in others there was none formed. Sometimes the injury preceded a fall, in others it was the result of one. In dealing with fractures of the neck and of the thigh-bone, the fibro-synovial envelope of the cervix was often left unconsidered. This structure, which he preferred to call Stanley's ligament, was of great importance. On its integrity the result of fracture of the cervix largely depended.

The fibro-synovial covering had but very feeble and osteogenetic power. Want of union was often due in old persons to osteoporosis, but it was a mistake to suppose that the angle that the neck of the femur made with the shaft was altered in this disease. The specimen before them showed this clearly, as Humphry had already pointed out. Fracture was not due to any alteration of angle. The change in shape of the lower jaw in old persons was often quoted as a parallel case, but the analogy was a false one. The deformity of the jaw was due to unopposed muscular action, the teeth having been lost and the muscles continuing to act without enough resistance to balance them. He thought that the old classification of fractures of the neck of the thigh-bone into intra- and extra-capsular was clinically good. The former class he would divide into those with and without penetration. Extra-capsular he would divide into those with and without impaction. By means of a lantern-slide photograph of a specimen he showed that the angle of the cervix might be increased in impacted fracture. It was to be noted that very tall people had cervixes more oblique than usual—for instance, the thigh-bone of Magrath, the Irish giant, which he showed.

The nearer to the head of the bone the fracture was the less chance there was of union. Eversion of the limb was due to rotation of the shaft of the bone over a hinge situated in the anterior wall of the neck at the point of fracture. Inversion, when it occurred, was due to the position of the limb at the time of accident. The differential diagnosis of these fractures was most important to the surgeon and to the patient. The

usual treatment adopted only tended to separate the fragments. As to routine treatment the practice of laying the limb on a pillow and in fact doing nothing should be entirely abandoned. He referred to Senn's experiments. The good results obtained by the use of ivory and bone nails showed, in his opinion, that the more perfect the fixation the more certain the union. It was, therefore, most unwise to attempt to disengage the impacted fragments. The outcome of Senn's experiments was the splint here shown, which carried a screw pad by which carefully graduated pressure could be brought to bear in order to keep the fragments in apposition. In Erichsen's "Surgery" it was said that in an impacted extra-capsular fracture there was no hope of restoring the limb to its normal length and position, and the patient must be left lame for life. Southam, of Manchester, however, in a young person, had broken down the impaction and got a good result. This was only a single case, and the procedure was not often applicable, and not at all in old persons. Union did sometimes occur in intra-capsular fracture, but in these cases he believed that Stanley's ligament was not penetrated. He thought that Bryant's double splint or his own screw extension splint was the best apparatus. The latter allowed the patient to sit up while keeping up moderate extension. This was a very great advantage, especially in old persons. There were two essentials in a good splint: 1, It should allow the patient to sit up; 2, the extension should not be more than to secure immobility.

Conclusions: Alteration of the axis of the neck does not occur, and is therefore not a cause of fracture. Absorption is due to osteoporosis preexisting, and in contusions to its being set up. Distinction and classification are of importance. Bony union is possible in all situations. The nearer the fracture to the head the less the chance of union. In treatment, fixation, rest, and moderate extension are desiderata.

In the discussion that followed Sir George M. Humphry said that there was not much left to add to what Sir W. Stokes had said. He would state it as an axiom that fracture in any part of the body and at any age will almost surely unite if kept at rest with the fragments in apposition. The cervixes of the femurs in old people were altered by senile absorption due to diminished power of resistance to the absorptive cells which were normally present in the cancelli. The upper part of the femur was peculiarly dependent for its strength on the cancellous structure. An interesting point was that, despite these senile changes, the osteogenetic cells in the bone did not lose their powers. Non-union was rare after fracture at the base of the neck. Much bone was generally thrown out there, and as the specimens produced showed, it was often superabundant. Intra-capsular fracture was commonest at the narrowest part of the neck close to the head. Non-union in such cases was not due to the want of bone-forming power of old people, or to deficiency of blood-supply. All parts of the skeleton had blood-supply enough for their repair. Failure to unite was largely due to the impossibility of overlapping of fragments in this situation. It was an established fact that overlapping bones almost always unite, and that firmly. Secondly, it was due to the fact that the new bone-forming cells were not detained by the soft parts in the neighborhood of the fracture, but were set free in the cavity of the joint capsule. If the tragments be kept in apposition they will surely unite. He showed a specimen in which a fracture close to the trochanter had united firmly, although the patient was eighty years old. A section through the bone showed firm union. The retaining fibro-synovial membrane was thicker in front, but it was also closer to the bone and more liable to be torn than at the back, where it was loose. Whether torn or not, however, the result was much the same. Contact between the broken surfaces was the essential thing.

Absorption occurred almost exclusively in the outer fragment, between the site of fracture and the trochanter, not between the fracture and the head of the bone. This process might be very rapid. Almost the whole neck of the femur might disappear in two or three weeks. He showed a specimen illustrating this liability of the outer fragment to absorption. The neck had entirely gone, while the broken surface close to the head was unchanged and still bore a projecting spicula of bone that (as often happened) had split away from the under side of the neck. This absorption was due, he said, to rubbing, and to the abundance of osteophage cells and weakness of resistance to them.

Mr. Bryant agreed with Sir W. Stokes, although he thought that the tabulation of these fractures into the eleven varieties referred to was not of much clinical value. Nor did he think that the distinction between intra- and extra-capsular fracture was clinically important. The really important question was whether the fracture was impacted or not impacted. Most of these fractures were originally impacted, but the impaction was destroyed afterward, either by the active or passive movement of the limb.

He agreed that the cause of inversion in certain cases was the position that the foot happened to be in at the time of the breaking. Immobilization and moderate extension were the ends to aim at. He had had forty-two consecutive cases of the average age of seventy; all had left hospital with good and useful limbs. Bed-sores were practically unknown. He could not pretend to say whether there were intra- or extra-capsular fractures. Very gentle examinations only should be allowed, and no attempt made to obtain crepitus, which was not needed for diagnosis.

Southam's case was a striking exception. He (Mr. Bryant) had had one patient, aged thirty, in whom there was inversion of the limb and impaction of the fragments. The case looks like one of dislocation. Considering at that age that it was wrong to condemn the patient to be a cripple for life, he loosened the impaction under an anæsthetic and rotated the limb out. The result was very good, but an enormous amount of callus was thrown out. In such exceptional cases it was justifiable to gently break down the impaction. The do nothing treatment was unjustifiable.

Dr. Bennett, of Dublin, said that he would take a wider field than the previous speakers had done. He would include fractures below the trochanters. He had twice produced intra-capsular fracture of the neck in attempts to produce dislocations onto the dorsum ilii, by forcible adduction in cadavers of seventy to eighty years old.

Mr. Greig Smith thought that there was some risk of elevating a rare variety into a separate species and of drawing clinical references therefrom.

An important division was that into fractures caused by indirect vertical violence at any part of the neck and fractures from direct transverse violence applied near the trochanter major. The degree and direction of obliquity of the fracture was most important both as regards immediate reduction of deformity and final result.

It was to be remembered that only part of the head of the femur bore against the acetabulum in the erect position of the body, and the obliquity of the line of fracture and eversion of the limb depended on this. Non-union was due to the absence of a nidus for the formation of new bone. We were too apt to forget the rôle played by the soft parts, and more especially by fibrous tissue in the repair of fractures.

He asked for a simple classification and would especially classify the obliquity. The fracture might be oblique downward and outward, and in that case there would be no shortening.

Mr. Mayo Robson said that in his opinion an elaborate classification was only possible in the post-mortem room. It was of small clinical value. The pres-

ence or absence of impaction was the really important thing. He believed that wherever there was opposition there was union. He would disturb the parts as little as possible, and apply the long splint with extension. If, however, recumbency was badly borne, Thomas's hip-splint was useful. As regards Southam's case, no doubt many surgeons had had such cases where breaking down the impaction in young persons was advisable, and had proved useful. In such it was not justifiable to let things alone. An important point was to find out the best method of treating these difficult injuries.

Professor Sinclair thought that the specimens showed that bony union was commoner than was generally believed. Intra-capsular fracture was often caused by external rotation, in which case the periosteum was not torn, and union resulted. When, however, the fracture was caused by vertical force, the weight of the body continuing to act after the bone had given way tore through the periosteum.

Sir W. Hingston, of Montreal, said that he was surprised to hear a general opinion expressed that union was common and shortening rare. The experience of surgeons in America was entirely different. Actions against surgeons for malpraxis in the treatment of fractured femur were so common that it had been found necessary at one of the great surgical gatherings in the United States to express the conviction that some amount of shortening was unavoidable. He was delighted to hear that in this metropolis surgeons were so successful. He feared, however, that general practitioners in the country would still have to screen themselves behind the American pronunciamento rather than the cheering dictum of accomplished London surgeons.

Mr. Gant thought that shortening was almost universal.

Dr. Weekes, of the United States, said that he held the classical views as to the classification and causation of these fractures. He thought that Liston's long splint with a hip-piece to prevent rotation, or else a long sand-bag, was the best thing to use.

Mr. Keetley said that in young people he would treat fractures of the upper part of the femur just like other fractures. He described a case of fracture of the neck of the femur on which he had operated. He had found the head ankylosed to the ilium and to the mushroom-like end of the neck by new bone. Removal of the head and of the mushroom-like growth gave a good result. Sir William Hingston's delicate sarcasm was perhaps justified. It was, however, so kindly put that while we appreciated it we were not hurt by it. Still, however, he held that it was a fact that in London, in fractures of the femur, those of the neck excepted, shortening was rare. Indeed, he had been looking for the last year or two for cases of shortening in which to use his pins, but almost without success. He showed the pins that he used for such cases and also in recent oblique overlapping fractures. These consisted of two L-shaped pieces of steel, one arm of each of which was passed through a hole made in the bone with a brad-awl, beyond the fracture, the other arms being lashed together with wire while the bones were held in the correct position. An anæsthetic was of course necessary for this operation. The results had so far been excellent.

Sir William Stokes then closed the discussion. He did not agree with Sir George Humphry that the blood-supply to the bones was always enough. If the ligamentum teres were torn through, the supply to the head could not be enough. Several speakers had taken exception to his classification, but he thought their objections were not well founded. We must go to the dead-house for our pathology. *A propos* of Sir William Hingston's remarks as to the prevalence of shortening in America, they were too sweeping. Dr. Senn had stated that with his splint he got results without shortening. He thought that Keetley's pins were too weak and flexible for their purpose. Wood's rather similar contrivance appeared to him to be stronger and better.

Floating Kidney.—Mr. Kendall Franks, of Dublin, then read an interesting paper on the "Pathology and Symptoms of Movable Kidney," clearly illustrated by lantern slides. There were several theories current as to the causation of this condition. Tight-lacing and menstrual congestion were said to cause it. Newman's theory was that during violent muscular efforts, such as occurred in parturition or in lifting heavy weights, the kidney might be squeezed between the psoas and quadratus lumborum muscles and shot out of its place, just as a bean may be shot forth from between the finger and thumb. Mr. Franks thought that he would be able to show that this theory would not hold water. In an inquiry into this subject it was first necessary to find out what kept the kidney in its place in health. Dr. Cunningham and he, by means of injections of Müller's fluid and of spirit several times repeated, had succeeded in hardening the kidney *in situ*, and thus fixing the form which it held in the unopened abdomen. On examining the anterior surface of the kidney thus treated, it was seen that this was not smooth and rounded, but that it presented always a transverse ridge, above and below which the surface sloped backward. Viewed in profile from the outer side each kidney appeared to be formed, as it were, of two almost right-angled triangles placed base to base, so that its posterior surface was flat. It would appear that the kidney, by the pressure of other organs, the liver above on the right side and the spleen on the left, was wedged into position by two forces acting in a backward direction. On the posterior surface could be seen depressions caused by the twelfth rib and the psoas and the quadratus lumborum muscles. Other forces tending to prevent its movement were the connective tissue and the fatty capsule. This last, he believed, had not much influence, for it must be remembered that at the temperature of the living body the fat was fluid. He believed that a loss of balance in the abdomen after parturition was the commonest cause of movable kidney.

It was well known that the intra-abdominal pressure, which was previously positive, became negative on delivery and remained so for some time afterward. Getting up too soon from child-bed was the determining cause. The symptoms differed on the two sides, but dragging pain and malaise were symptoms common to both. On the right side, indigestion, abdominal pain, flatulence, and vomiting were complained of. No variety of food or regulation of diet and no medical treatment affected these gastric crises; the symptoms, indeed, strongly resembled those of stricture of the pylorus. The cause of these symptoms was made clear in a case of Mr. Franks's on which he operated. The kidney was found in the right iliac fossa, having in its descent dragged down the duodenum by means of an adhesion, so that the gut was kinked and almost completely occluded. In some cases the adhesion is less tight or longer and there is no kinking. On the left side the symptoms are not so marked or special, but occasionally obstinate and intractable constipation occurs. On operating on such a case he had found the kidney enveloped in the colon, which it had dragged down and which had fallen over the front of it. Fixation of the kidney by suture entirely removed this symptom, and the bowels afterward acted regularly and without trouble.

Mr Bland Sutton said that jaundice was sometimes a symptom of movable kidney on the right side. The diagnosis of movable, or rather of floating, kidney was often wrong, and on opening the abdomen it was found that the symptoms were due to other conditions, the kidney being normally fixed and situated. A movable kidney is not free to roam about the abdomen in

all directions: its movements are limited to an upward and downward direction, and it slides in a channel like a mole's "run" behind the peritoneum.

SECTION OF SURGERY.

SECOND DAY, THURSDAY, AUGUST 1ST.

True Ankylosis.—MR. HOWARD MARSH read a paper on the "Pathology and Clinical History of some Rare Forms of Bony Ankylosis." He described certain cases of tubercular joints that had come under his observation, that had run their course without suppuration and had ended, as shown on subsequent excision, in bony ankylosis. The bones removed from an elbow were shown to the meeting. This kind of plastic inflammation running on to organization of inflammatory products without suppuration, occurred, he believed, also in the spine. He showed a specimen of ankylosis of the atlas and axis that he said supported this view. It was a question whether bony ankylosis might not occur in Charcot's disease. He thought that it might without suppuration, and quoted a case of Charcot's where the foot was affected. In this foot the cuneiform and metatarsal bones were ankylosed. The two skeletons of feet shown had been lent to him by Professor Humphry. In these there was bony ankylosis and the surfaces of the bones were covered with vegetations and bony deposits, the joint surfaces being little affected. The history of this specimen was unknown. It was difficult to believe that the changes were the result of pyæmia. He had observed a case of injury to the median nerve that was followed by stiffness and bony ankylosis of a finger joint without suppuration.

There was no doubt that bony ankylosis followed sometimes on gonorrhœal rheumatism, and that it also occurred in the spine in scoliosis. He had seen a case in which throughout the lower extremity the joints were ankylosed by bone. It was common in osteo-arthritis in the spine, unlike other joints in that disease. The joints themselves were intact, but the ligamentous tissues were ossified. The process was sometimes reparative, as when it occurred in acutely inflamed pyæmic joints or in tubercular joints, and sometimes degenerative, as in Charcot's disease and in gout, and in the feet lent by Sir George Humphry, and when ligaments were ossified.

MR. TARGETT said that these cases of ossification of ligaments much resembled myositis ossificans. In one of the specimens shown to-day the ligaments were clearly defined in new bone, the anterior common and costo-transverse ligaments being quite clear and distinct. In Charcot's disease there was atrophy of the bone; if this were not present, the case was probably not one of Charcot's disease. After the joint inflammations of puerperal fever, bony ankylosis was often rapid and complete.

MR. BOWLBY said that in the case of injury of the median nerve alluded to, many fingers were ankylosed. The changes which took place in the joints after nerve injuries were very like those of rheumatism, but bony ankylosis was not common and ligaments were more liable to be affected than were joint surfaces. There were changes in the joints in many nerve diseases besides tabes. He believed that some day certain now little understood joint lesions would be recognized as the result of definite nervous lesions.

MR. BLAND SUTTON said that similar changes occurred in the spines of horses. He did not believe that the atlas and axis shown could be tubercular, because of the age of the patient. Tubercle started in the junction cartilages before ossification was complete. Further, every museum contained specimens of occipito-atlo-axoid ankylosis. These specimens had usually no history, but were found in cemeteries, and one he had seen that was removed from an Egyptian mummy. Arbuthnot Lane had said that this condition occurred in costermongers, and was the result of carrying a load on the head. It had occurred to the speaker that if that were the case, a similar condition should be found in cattle which carried the yoke on their horns, as was customary in some places. He had visited the Veterinary Museum at Alfort and had found several specimens there. He could confirm Mr. Marsh's description of these cases where the anterior common ligament was ossified. Those specimens were generally labelled as rheumatoid arthritis. The condition was a very common one in the horse. There were numerous specimens at Alfort and in the museum at Camden Town. In men no symptom beyond stiffness of back and stooping were complained of; but in horses there was great danger, if they were cast for any purpose, that in the struggle to rise again the spine might be fractured and palsy ensue.

MR. ELLIS, of Gloucester, pointed out that the great toe affected in the specimen was in the position of rest, that of valgus. Those joints most exposed to irritation were most liable to ankylosis.

MR. HOWARD MARSH, in reply, said that, as to the specimen of the first two cervical vertebræ, he must absolutely differ from Mr. Sutton. Tuberculous disease of the spine might occur at any age. He instanced the case of Dean Buckland, who died of atloaxoid disease at the age of eighty. He thought that if Mr. Sutton had ankylosis of his own vertebræ he would not speak of the affection as trivial and causing no trouble. In these cases the patients were rendered helpless and unable to rise from the horizontal position.

A Hiding Place for Vesical Calculus.—MR. G. BUCKSTON BROWNE then read a paper in which he called attention to a hitherto undescribed locality in the male urinary bladder, where a stone may lie and elude contact with any instrument passed through the urethra. He said that in some cases where a stone had been suspected, it could not be found by the sound per urethra, yet on opening the bladder above the pubes it was found. In other cases a stone had been discovered with the sound, but on doing a perineal lithotomy it could not be found. In these cases the prostate was enlarged inside the bladder, generally backward, forming the middle lobe, and a stone might be hidden in the pouch behind this which he had before described. In some cases, however, there were lateral enlargements of the intra-vesical portion of the prostate, and a stone might be hidden in a pocket between one of these and the bladder wall. In two cases he had found, on opening the bladder above the pubes, that this was the case. In the first case, he was occasionally able to touch the stone with the sound, but never could seize it with the lithotrite. After several attempts the supra-pubic operation was performed, and the stone found in the right lateral pouch described. In the second case the urethra was eleven inches long. Blood followed all attempts at examination or catheterization. Under an anæsthetic, he succeeded in finding a stone. The bladder was distended with solution, which was retained by means of an elastic ligature on the penis which prevented escape of fluid at the side of the lithotrite. In this way he was enabled to crush the stone. A few months afterward symptoms of stone returned. He could not detect a stone by any means at his disposal. The bladder was, however, opened above the pubes, and a stone found in one of the lateral pouches. That first crushed had probably lain on top of it. He advocated distension of the bladder and lithotrity in cases where supra-pubic lithotomy was too severe a proceeding. This failing, he would try to dislodge the stone by suction through the evacuator, to which an aspirator was attached. He found that Cadge, of Norwich, whom he considered the greatest authority on stone, had alluded to this lateral pouch in his lectures, some years ago, at the Royal College of Surgeons.

Mr. Mayo Robson described a case where a large, hitherto undiscovered, stone was found, on suprapubic operation, to lie in a pouch in front of the intra-vesical lobe of the prostate. In another case several stones were extracted with difficulty from a pouch behind the prostate.

Mr. Buckston Browne thought Mr. Robson's first case must be unique.

Treatment of Neoplasms of the Thyroid Gland.—Mr. Butlin then opened a discussion on "The Surgical Treatment of Cysts, Tumors, and Carcinoma of the Thyroid Gland, and Accessory Thyroids." Malignant disease of the thyroid was not amenable to operation. These tumors grew very rapidly and infiltrated neighboring tissues very early. Cysto-adenoma was not uncommon. The surgery of the thyroid had advanced very rapidly during the last few years. This improvement was due to pathological study. Thanks to this it was now known that cysts were very common in the gland. All cysto-adenomas were innocent tumors separable and encapsuled, and the gland was healthy, as in the case of similar tumors in the breast. Our nomenclature showed a slowness to appreciate our newer knowledge. A so-called cystic goitre was not a goitre at all, the gland itself being unaffected. The operation for the removal of these cysts was simple. Drainage was needed for the first few days, owing to the presence of a cavity. Sosin's operation of enucleation was applicable to all partial enlargements of the gland, unless it dipped down behind the sternum. He described a case that came to him in the out-patient room some time ago, which he aspirated; there was considerable bleeding, and oozing occurred whenever the dressing was removed. He had at last to lay it open and plug the cavity, which proved to be a large one. Such bleeding was due to vascular growths on the wall of the interior of the cyst. The scar that remained was an objection to the enucleation operation. He thought that the method of injection advocated by Morell Mackenzie, and described in detail in the "Transactions of the Clinical Society," was often most successful. He strongly recommended that Mackenzie's directions should be adhered to in using this method. Its object was to convert the cyst into an abscess and allow the matter to escape through a cannula until the cavity was closed. It was not applicable to hospital cases, on account of the time it occupied, but for the well-to-do who thought a great deal of the disfigurement a scar produced, it had a great deal to recommend it. The method had fallen into disuse, but he believed that the difficulties encountered were due to want of care in selecting cases. For instance, it has been used in parenchymatous enlargement with very bad results. Injection into the cavity of a cyst was safe, but into the substance of the gland it was not to be thought of. Large cysts and hemorrhagic cysts should not be injected, nor those in delicate and strumous persons, nor should old-standing cysts with thick walls. A moderate amount of intra-cystic growth was not a contra-indication to injection.

Dr. W. W. Keen, of Philadelphia, said that thyroid disease was not common in America, and therefore his experience was not great, but he had recently visited Switzerland and had observed the practice of Swiss surgeons in operating on the gland. No anæsthetics were used except in the case of young children and very nervous women. Five out of six of the cases he saw thus operated seemed to feel very little pain, and the bleeding was much less. Kocher used a transverse incision curved with the convexity downward. The scar of this showed less than a median vertical one. To minimize scar he recommended the subcuticular suture recommended by Dr. Halstead, of the Johns Hopkins Hospital. He thought that the minute attention paid to the arrest of hemorrhage in Switzerland deserved to be imitated. Scarcely two ounces of blood were lost in an operation. Kocher's actual work exactly corresponded to his published method of operation in all its details.

Mr. Charters Symonds said that he had had forty-four cases without a fatal result. Twenty-nine of these were cases of adenoma. He thought that certain cases of malignant disease in an early stage might be benefited by operation. In advanced cases tracheotomy was often needed as a palliative. He preferred a median incision to the oblique lateral incision. If the cyst on exposure appeared white, it might be fearlessly excised. If, however, it were purple it was probably almost solid from intra-cystic growth, and alarming bleeding might be expected at first. This, however, could be promptly stopped by everting the wall of the cyst and seizing the bleeding vessel. He preferred to operate under an anæsthetic. He had never encountered serious bleeding. He kept a drain in for only twenty-four hours. He did not hesitate to remove cysts that slipped down behind the sternum. He thought that Mr. Butlin's selection of cases for injection was a good one, but cysts without solid growth were very rare. The cyst wall was very thin where the growth was situated, and might give way when suppuration occurred. As to the scar, he made a small incision as low down as possible, so that it could easily be hidden. A very small wound would suffice if the cyst were punctured and emptied before removal.

Mr. Mayo Robson said that he had found packing the cyst answer well. He had heard of accidents after injection. Since he had read Mr. Symond's paper he had always removed cysts. He had no experience of the accessory thyroids. In his experience, cases of malignant disease were too far advanced when seen to be amenable to operation. In these cases distressing dyspnœa occurred, and it was difficult to relieve it. Tracheotomy was out of the question sometimes. He had found great relief from intubation. He had had difficulty in isolating certain cysts, and had sometimes been obliged to remove half the gland when there were many cysts. As to subcuticular suture, it minimized the scar. He did not think, however, that Butlin's objection to the scar was of great weight. Ether was not a good anæsthetic. It increased the bleeding and dyspnœa. He preferred chloroform or A. C. E. mixture. He would always give an anæsthetic, even if it were only continued till the skin incision were made. When in an operation on the thyroid tracheotomy became necessary as a temporary measure, it was a good plan to suture the rings together at the end of the operation and close the wound, leaving the sutures buried.

Mr. Berry had never seen a case of malignant disease amenable to operation. The layer of tissue immediately over the capsule of a cyst or tumor was almost always microscopically thyroid-gland tissue, however thin. Enucleation was only advisable when there was a single well-defined tumor. If the tumors were multiple or ill-defined extirpation was better. The more nearly the tumor approached to the globular form, the more likely that it could be enucleated. The more pyriform it was, the less likely to be fit for enucleation. Smooth regular-surfaced tumors may generally be enucleated. He described a case of large substernal tumor that he had successfully removed. The tumor scarcely showed above the sternum.

Mr. Keetley had operated on two cases of malignant disease, also three times without an anæsthetic. In one case of a very large tumor the anæsthetic was stopped as soon as the skin incisions were done. He was not so clever as the abdominal surgeons who would clear you out a pelvis in three minutes or so, and this operation occupied three hours. The patient was unrestrained throughout, yet did not interfere with his hands or struggle in any way. She suffered hardly any pain except when, owing to the difficulty of raising the tumor in order to free it behind, where it was adherent to the trachea and larynx, he had to divide its wall and scoop out the contents in order to allow

it to collapse. The question of malignant disease was too wide a one to go into here thoroughly, but in their early stage these growths must be entirely encapsuled, and could we but diagnose them early enough they might be removed. Attention was clearly needed to early diagnosis. The increased tendency of surgeons to operate on the thyroid must surely lead to operations on early malignant tumors. The improvement of late years in our treatment of the thyroid was due to pathological knowledge acquired *in vivo* instead of *post mortem*. He did not approve of the injection treatment. He thought so serious a thing as a cyst in the neck should be treated through an adequate open incision. No drain should be necessary. If there were a collection of fluid a day or two after operation, it was easy to insert a probe and give it vent.

Mr. Barker had succeeded in removing large malignant tumors of the thyroid. In the first case the growth formed the largest tumor of the neck that he had ever seen. More than one surgical authority had advised against operation five years before. He had to make an incision over thirteen inches long from the mastoid process to the episternal notch. The glands were found to be involved and were removed, so that the pleura was exposed at the bottom of the wound. The patient recovered. Two years afterward recurrence occurred in a gland that had escaped removal. This was excised, and the patient was still alive six years after this last proceeding. In another case also he had successfully removed a malignant growth. He thought that there was no doubt as to the nature of the growth in either case.

Mr. Jordan Lloyd said that he thought that enucleation was an easy proceeding, until he encountered two cases of quite unenucleable cysts containing solid growths. In many cases the hemorrhage was trivial, but it might be alarming. He thought that Mr. Barker's cases were something very different to the cases of malignant disease referred to by Mr. Butlin and other speakers. The long duration of the disease in Mr. Barker's first case was a most curious and interesting fact in the history of the thyroid. That a patient with an undoubtedly malignant tumor should survive to be operated on five or six years after she had been pronounced too far gone for operation, was simply astounding. He shared the belief of other speakers, that malignant tumors of the thyroid in the present state of knowledge were not fit to be operated on. The dangers of the injection treatment were immense. He thought very little of the objections to open incision on account of the scar. A transverse incision low down in the neck was applicable to many cases, and the scar was not obvious.

Mr. Thelwall Thomas said that he had operated on two cases of accessory thyroids. In one lumps were removed from behind and beneath the sterno-mastoid, and below the angle of the jaw. The microscopical appearances were those of thyroid-gland tissue. In the second case there was a tumor above the clavicle in the posterior triangle. It proved to consist of cystic thyroid tissue, the gland itself being normal. It was easily removed. Scars were due, he thought, to the line of incision crossing the natural folds of the neck. What soon after operation seemed to be a linear, almost invisible scar, became broader and more marked if the incision were across the folds, but if it were parallel it scarcely showed.

Mr. R. C. Chicken deprecated the use of iodine and other irritants to swellings in the neck. They did no good, and often increased the difficulties of subsequent operation. The only case of trouble from bleeding that he had had was due to the use of that most unreliable and most treacherous of surgical devices—the Staffordshire knot. It was only of use when it was wrongly tied. In severe dyspnœa section of the isthmus was most serviceable.

Mr. Cathcart reminded his hearers that one cannot draw the line clearly between innocence and malignancy. Hence arose the divergent views of Mr. Barker and other speakers.

Mr. Butlin, in reply, said that so far as congratulating Swiss surgeons on only shedding two ounces of blood, he should be ashamed himself of such hemorrhage. Two drachms was more like the average in his cases. One objection to the transverse incision was, that where the scar was visible it suggested the last penalty of the law, and might lead to unpleasant remarks. He always avoided puncture of the cyst, because it made removal more difficult.

Third Day, Friday, August 2d.

Intestinal Anastomosis.—The proceedings began with an interesting demonstration on the cadaver by Dr. Murphy, of Chicago, of the method of using his buttons. It is impossible here to describe the demonstration, which was watched with great interest by many surgeons. Dr. Murphy pointed out that perfect coaptation of surfaces was necessary. The desiderata were, 1, perfect coaptation of surfaces; 2, immediate adhesion; 3, sufficient calibre after separation of the button; 4, permanent organization of the uniting material; 5, avoidance of contraction afterward; 6, maintenance of asepsis; and 7, speed in performance of operation. When all seven were attained we had an ideal operation. By his method edge-to-edge union was obtained, not lateral approximation, for the inverted portions are cut off by pressure atrophy. Microscopic examination after union showed this to be the case. He claimed that the connective tissue was only temporary, and that it was ultimately replaced by reproduction of muscular and other layers of gut, so that in the end there was no scar and no contraction. There were certain points about the blood-supply of the intestine worthy of attention. There were two principal sources, one the radiating mesenteric vessels, the other a collateral or parallel supply. It was found by experiment that the mesenteric vessels might be ligatured for a space of seven inches without necrosis following; but, on the other hand, we could not arrest the circulation through the lateral vessel along the bowel for more than half an inch without producing necrosis. Some failures of union were due to neglect of this. More of the bowel should be removed on the convex border than on the mesenteric, and care must be taken not to include too much of the gut on the convex side. The point of attachment of the mesentery was a weak point in using the button in end-to-end approximation. A figure-of-eight stitch should be placed across this place, so as to draw the two layers of peritoneum closely round the bowel and button. In inserting the button, the female half should first be placed, and in putting in the male half it should be grasped by its outer flange. It was necessary to see that the edge of the mucosa was all within the grasp of the button, otherwise one might get mucosa applied to serosa, with resultant non union. On opening the abdomen it was easy to tell in which direction the upper end of the gut lay. If the hand were run along the mesentery and the latter were found to be attached to the right, the true upper end of the bowel would be found to lie below, and *vice versa*. The mesentery should be ligatured close to its base, and one ligature would do for many inches of gut. The thread should never be pulled tight before making the knot, otherwise the bowel may be torn. The halves of the button should be slowly and steadily pressed together until the "click" was heard. Openings in the gut should be two-thirds the size of the button. For resection of the rectum a special long, cylindered button was to be used.

Cervical Spinal Surgery.—Mr. Victor Horsley read a paper on "The Results of Operative Treatment of Injury or Disease of the Cervical Vertebræ." He had performed laminectomy in seven cases of caries and

fracture of the spine in the cervical region with paralysis. He had had one death, but all the patients recovered from the operation. He exhibited three patients to the Section.

Case I.—Caries of atlas and axis, palsy of all four limbs, and beginning of palsy of respiration. Skin dusky and respirations thirty-six per minute. In 1888 he removed the arches of the first and second cervical vertebræ. Six days after the operation power began to return. Wasting of the interossei of the hands was very marked, as in all these cases. It was still noticeable, although it was seven years since the operation.

Case II.—Caries of fifth and sixth cervical vertebræ. Palsy marked but not complete. Reflexes exaggerated. Sensation normal. Recovered after laminectomy.

Case III.—Absolute motor palsy of lower limbs and of right upper limb. Anæsthesia up to third rib. Reflexes absent on right side, exaggerated on the left. Removal of arches of third to seventh cervical vertebræ. Began to recover in three days.

In all cases he had noticed rapid recovery after the third day from the operation. Ephemeral recovery was often noticed. This might be explained by the occurrence of temporary œdema.

Case IV.—Fracture of cervical spine from a fall five months before the operation. Palsy of all four limbs. Slight recovery. Then became worse. Angle at spines of fifth and sixth cervical vertebræ. Sensory palsy was severe. There was even analgesia denoting injury to the central gray matter. Reflexes were exaggerated and the rectum paralyzed. There was contraction of the knees. Quite recovered after operation and removal of fibrous tissue and forcible extension, but the interossei were still rather wasted.

Case V.—Fall from a cart. Walked after a week. Bodies of fifth and sixth cervical vertebræ fractured. Treated at various hospitals for symptoms, but there was no deformity in line of spinous processes. Motor and sensory palsy, and some analgesia and vesico-rectal paralysis. Reflexes exaggerated. The left optic disk was swollen, possibly commencing optic neuritis. Operation: Removal of arches of fifth, sixth, and seventh cervical vertebræ. The body of the sixth was found to be crushed and fragments driven back. Forcible extension and consequent abolition of ridge. Recovered by the twelfth day. Recovery permanent.

Case VI.—Tossed by a bull. Fracture. Gradual onset of palsy. Lower half of cord involved. Anæsthesia of post-axial part of upper limb and of patches on lower limb. Vesico-rectal palsy. Operation similar to Case V. No ephemeral improvement. Palsy was more marked after operation (due to œdema?). Recovery slow and not yet quite complete.

Case VII.—Fall from a car on to the forehead. Got up and walked two hundred yards. Tried to walk upstairs, but could not. Rapidly became paralyzed in all four limbs. Some recovery afterward took place. When seen by Mr. Horsley had spastic rigidity of limbs. Had some voluntary movement, but it varied. Slight deformity of spine. Post-axial anæsthesia of upper limbs. Exaggerated reflexes. Laminectomy and ephemeral recovery. Permanent recovery three weeks after the operation. Can now walk a mile and is still improving. This patient gave up his support too soon and spasm began to reappear, but disappeared again on reapplication.

Mr. Horsley referred to alarming phenomena which might appear after laminectomy in the cervical region. In some cases the temperature rose to 104° F. and the pulse to 130. He let out the cerebro-spinal fluid from the wound and the temperature fell at once.

The President said that the patients exhibited were surgical triumphs. He would ask for information as to the gradual onset of symptoms in certain of the cases, and in cases where the palsy was immediate he would ask how we were to tell whether the damage done were or were not irreparable.

Sir William Stokes asked Mr. Horsley to explain how in caries removal of the laminæ gave permanent relief, when in this disease the bodies alone are as a rule affected. He would like to hear something as to the condition of the bones that were removed. In cases of fracture the operation was unpopular in Dublin. How was permanent extension provided for in the case recorded in which extension was found possible on operation?

Mr. E. Noble Smith said that in cases of caries it was important to know when operation was necessary and when recovery might be expected without it.

Mr. Keetley has had two cases of laminectomy, one of them for cervical fracture of the spine. In one the fifth cervical vertebra was pressed back on to the fourth. Paralysis was immediate. He removed the lamina of the fourth cervical. There was some improvement, but on the fourth day the patient died. At the necropsy the cord was found to be clearly divided although the dura mater was intact. In the second case, of a boy aged eighteen, there was long-standing complete paraplegia from caries. The condition was improved by gypsum corset, but the improvement was transitory. Laminectomy over the projection did not seem likely to do good. He therefore attacked the bodies through the pedicles and heads of the ribs. No abscess was found and the bodies, as far as they could be examined, were sound. The patient was many months in hospital. He went home and finally recovered, as nearly all such cases do if left alone. Mr. Horsley's experience of these cases was greater than that of anyone present except Professor McEwen; but Mr. Keetley ventured to think that in the case of caries extension would have done as well without the preliminary laminectomy. Cervical laminectomy was a very serious operation, more so in surgery. Immediately after a fracture it was very difficult to decide as to need of operation. Examination was dangerous, for the slightest movement of the parts might prove fatal. Laminectomy was almost the only operation in which we approached the disease from the most dangerous side with structures of the greatest importance intervening. Why not operate on the cervical spine from the front and side?

Mr. Damer Harrison said that hyperextension of the neck was most valuable in fracture. He thought that some of Mr. Horsley's cases would have recovered with this treatment alone. It was impossible to tell what amount of injury was inflicted on the cord. For instance, in one case he had known palsy come on three days after the accident. Laminectomy failed to relieve the symptoms. The dura mater was not opened. After death, the outside of the cord showed no sign of injury to the naked eye, but on section hemorrhage in the gray matter was found.

Mr. Luke Freer asked for more information as to the stage of the disease in the case of caries recorded, and the duration of the paralysis. These cases almost always recovered in time.

Mr. Mayo Robson had done laminectomy for caries, and found three vertebræ bathed in pus. The same patient afterward had fracture of the vertebra next above. The result was a very partial recovery. The cord was found to be half divided. Laminectomy did no good. If the cord were injured at the time of accident, he did not believe that laminectomy was of any use. If it were not injured, then recovery would occur without laminectomy.

Mr. V. Horsley, in reply, said that in acute cases, if there were complete motor palsy and abolition of deep reflexes, an operation was not justifiable. In caries, removal of the granulation tissue on the dura mater relieved pressure. He advocated elastic extension under the chin and mastoid processes, through steel spring supports fixed to a poroplastic jacket. In some cases operation was undertaken to save life, on account of urgent dyspnœa, etc. When paraplegia

was due to abscess, he would always operate and drain the abscess if necessary through the pedicles. Drainage must be kept up, or there would be no improvement from the palsy. When extension has been tried for some months without marked improvement, he would operate.

Colectomy.—Mr. Mayo Robson read a paper on "A Series of Cases of Colectomy." He said that four out of five cases recovered. He believed that the use of his decalcified bone bobbin was a great improvement in the operation of cholecystectomy. He used it also in acute obstruction and for lateral anastomosis. With the bobbin the operation could be done as quickly and as safely, or more safely, than with Murphy's button. In some cases, it was a good plan to paint a thin coating of shellac round the central portion of the bobbin so as to delay dissolution. There had been thirteen cases in the Leeds Infirmary, under five different surgeons, with a mortality of twenty-three per cent. He thought that this might be taken as the real rate of mortality in this operation.

Mr. Greig Smith said that he believed it was best to bring the tumor and stricture outside the wound and fix it by means of a skewer; incise the bowel and drain it and operate on the stricture later on when the abdomen was again flat and the bowel not distended and had recovered its tone. No anæsthetic was needed for the second stage of the operation. He described three cases which could not have borne resection at time of preliminary incision, but all recovered after deferred resection operation without a bad symptom. The deferred enterectomy was much easier with the bowel outside the abdomen. In one case of acute obstruction with a small malignant stricture, he used Murphy's button. All went well for two days. The patient then died. The button was found to be all right, but the patient was not fit for the operation. Had he divided the operation into two stages, he believed that the patient would have recovered.

Dr. W. W. Keen, of Philadelphia, described a case of failure with Murphy's button. He could not get the two halves to close on one another with any amount of force that he dare apply. The patient died. The gut was found to have sloughed over the upper half of the button. The obstacle to approximation was caused by the catching of the end of the thread, showing the importance of attending to Murphy's direction that the thread should be cut short after tying.

Mr. Herbert Allingham had had eight cases of resection, of which four died. All were combined with obstruction. He had determined in future to drain these cases first as recommended by Mr. Grey Smith. He could not, however, agree with that surgeon as to the painlessness of removal of the stricture gut. He found the mesentery very sensitive, and that there was marked shock on cutting. He much preferred Robson's bobbin to Murphy's button.

Mr. Harrison Cripps heartily indorsed what Mr. Grey Smith had said as to the advantages of the operation in two stages. He thought that no patient with actual obstruction was fit for resection. As to Murphy's button, he thought it the most fatal way of treating obstruction. It was used in four cases at St. Bartholomew's Hospital, all of whom died. In two of these the button had nothing to do with the result. Of the other two, one died on the eighth day. The junction was complete. The button had passed down the bowel for six inches and had then stuck fast and ulcerated through, causing death from fecal extravasation and peritonitis. In the other case, the intestine had sloughed where it was stretched over the button. He thought highly of Mayo Robson's bobbin, but believed that the finger was the best guide in suturing; there was no need to hurry, and a careful and accurate approximation and suture of the two ends could be made.

Dr. Macewen said that in surgery he was generally a radical, but on this subject he was a conservative. He had relied in the past on sutures and sutures alone. He would not say that he would never use the button or bobbin, but thought that further experience was required of their practical value. He liked the operation in two stages, but there were cases in which one could not get the tumor outside the abdomen as Mr. Grey Smith advised. He spoke of cases in which the control of the bowels was for long defective. This he believed to be due to removal of the ileo-cæcal valve.

Mr. Mayo Robson, in reply, said that he could not agree with Mr. Smith that the tumor could generally be easily drawn out of the abdomen, but he thought preliminary drainage very valuable when practicable. In enterectomy and pylorectomy simple suturing did well, but the bobbin was better. Its use secured continuity of the bowel-wall and avoidance of contraction. The important point was that the ends of the gut were united by sutures and not by the bobbin. The latter was merely a guide and a protection to the sutures for several days. Some of the specimens in the museum showed how Murphy's button might score the intestine in its passage down.

Colotomy.—Mr. Harrison Cripps read a paper on "A Complication Occurring in Inguinal Colotomy." The mortality in nearly every case was due to delayed operation. When the obstruction was complete it was difficult to get at the bowel and it would bear very little handling. It was difficult to stitch it to the skin without going into the muscular coat. In some cases there was difficulty in finding the bowel, but this difficulty diminished with experience, which had taught him that the best plan was to feel for the brim of the pelvis when the rectum would be found and traced to its sigmoid flexure, which in these cases lay much nearer the middle line than normal. Absence of a mesentery was a most unfortunate and dangerous complication. To this cause he owed all the deaths except one. The question arose, What was to be done under these circumstances? Should the operation be given up and the other side opened? The objection to this course was that owing to the fluidity of the fæces in the ascending colon, the management of the artificial anus was far more difficult. He preferred to suture the parietal peritoneum to the bowel. No attempt should be made to draw the skin down to the gut, but the peritoneum should be separated from the wall of the abdomen as far as necessary. The bowel might be opened at the mesentery and the cut edges sutured to the parietal peritoneum; but in this way the wound was apt to get soiled. This might be avoided by raising, as it were, flaps from the bowel, consisting of peritoneum and muscular coats, and suturing these to the parietal peritoneum. The mucosa should not be divided until two days afterward. The bowel was only likely to tear away when there was too short a mesentery. It was an excellent rule to draw out plenty of the gut, as had been taught by Mr. H. W. Allingham. A free opening was always desirable, and in many cases a spring dilator was required.

In one case, after colotomy, a rare complication occurred which ended fatally. The patient did well and recovered from the operation and was about to leave the hospital when he had a sudden attack of pain in the neighborhood of the artificial anus, accompanied by vomiting. As he described it, "Something slipped in his inside," and the pain and vomiting thereupon ceased. As he seemed quite well, he was allowed to leave the hospital, but he returned ten days afterward in a dying condition with the same symptoms and died soon after admission. At the necropsy it was found that a loop of small intestine had slipped between the attachment of the colon and the wall of the belly. Prompt abdominal section would have saved him had the meaning of the symptoms been understood. This case would be a warning to him in the future.

Hernia of the Sigmoid Flexure.—Mr. William Anderson then reported three cases of sackless hernia of the sigmoid flexure through the left inguinal canal, with anatomical specimen. He said that this variety of hernia arose from the absence of a mesentery, the gut being covered by peritoneum for only half its circumference. The bowel having stretched its connections, slips down in the sub-peritoneal tissue and passes easily through the internal abdominal ring which is not protected by parietal peritoneum.

Mr. H. Morris had made an attempt to form a mesentery in a similar case. Mr. Anderson thought it was advisable when operating to close the inguinal canal as completely as possible.

Splenectomy.—Mr. Spanton then reported three cases of splenectomy in his practice. Two of these were fatal, one had recovered. He submitted an elaborate table giving the details of 93 cases of this operation with their results. Twenty-five of these were described as leucocythæmic. Of these only 1 recovered, and this was classed by Mr. Knowsley Thornton under hypertrophy. This gave a death-rate of ninety-six per cent. Of the remaining 68 cases, 44 were cases of hypertrophy; of these 20 recovered; 12 were cases of wandering spleen; of these 11 recovered. Of the remaining 12 cases, all recovered except 1 (condition not stated); these included rotated, sarcomatous, and cystic spleens. The death-rate of splenectomy (exclusive of leucocythæmia) had improved from eighty per cent. in the decade 1865–75 to fifty-one; eighty-five per cent. in 1875–85, and to 19.35 per cent. in 1885–95.

In the speaker's first case (in 1883) death occurred from hemorrhage in seven hours. The spleen, which was hypertrophied, weighed 8 pounds 3 ounces. In the second case, in 1891, the patient died from shock in eleven hours; the spleen weighed 5½ pounds. The patient was very anæmic and the case very unpromising. She had suffered great pain and distress, and had wished for operation. In the third case he transfixed and doubly ligatured the suspensory ligament and the pedicle. The spleen weighed 6 pounds 4 ounces. There was rise of temperature and pains, referred to the situation of the pedicle, for some time. The operation lasted half an hour. In all three cases the operation was undertaken on account of hypertrophy. He thought that in future splenectomy should not be thought of in leucocythæmia. In hypertrophy the symptoms were so severe and rendered life such a burden that the operation was quite justifiable. The mortality had diminished very much of late years. He thought that in certain cases of wandering spleen also operation was justifiable.

Bladder Drainage.—Mr. Cathcart then exhibited and explained a simple apparatus for draining the bladder in cases of supra-pubic lithotomy. It consisted of an ordinary irrigator or douche can, the rubber tube from which, by means of a Y-shaped junction-tube, was made to bifurcate. One branch rested in the bladder, the other was interrupted by an S-shaped tube of glass, from which it ran to a receptacle on the floor. By means of a pinch-cock on the rubber tube close to the reservoir the flow of water from the latter was reduced to a mere dribble. This accumulated in the S-tube, and thus the urine in the bladder was drawn off by an intermittent syphon action.

Owing to the want of time the remaining papers in the programme were read by title, and this terminated the proceedings of the section.

Friars' Balsam, so successfully used during the Middle Ages in the treatment of wounds, ulcers, etc., doubtless owes its virtues to the antiseptic action of the benzoic acid it contained, although the part played by germs in wound repair was then unknown.

Therapeutic Hints.

Bronchitis.—

℞. Potassium citrate ..... ℥ss.
Lemon juice. ..... ℥j.
Syrup. ipecac. ..... ℥ij.
Aquæ ..... ad ℥iij.
M. S.: One-half ounce four or six times a day for an adult.

—H. C. Wood.

Sluggish Liver and Indigestion.—

℞. Acid. nitro-hydrochlor. dil. ..... ♏x.
Tinct. podophyllin ..... ♏x.
Succ. taraxaci ..... ʒj.
Tinct. nucis vom ..... ♏x.
Syrup. zingiberis ..... ʒss.
Aq. menth. pip. ..... ad ℥ss.
S.—In water three times a day.

Hydrotherapy in Fevers.—Winternitz, at the International Congress at Rome last spring, gave the results of some recent investigations of thermic effects on the composition of the blood in health. He demonstrated that all applications of cold to the entire or greater portion of the surface of the body, when proper reaction was secured, led to three remarkable results, viz., an increase in the number of leucocytes, an increase in the percentage of hæmoglobin, and an increase in the specific gravity of the blood. Local applications of cold, followed by reaction, accomplished the same results in the local blood-supply. This affords us now for the first time a rational instead of empirical basis for the employment of cold compresses and poultices.

Gout manifesting itself anywhere but in a joint is to be considered irregular or incomplete. — Duckworth.

Kraurosis Vulvæ.—Proceed as follows: a ten per cent. ointment of cocaine to be applied and bromides administered internally; at the end of a week the affected parts are to be painted with tincture of iron twice a week; under this treatment the burning and smarting soon diminished and the fissures healed. Next the parts were smeared with Lassar's salicylic paste, and finally tampons were applied soaked in a ten per cent. solution of ichthyolresorcin. In two months the parts assumed a natural appearance, and recovery was complete.—Bericke.

Chancroid.—Actual cautery and dress antiseptically:

℞. Acidi sulphurici,
Pulv. carbonis ligni ..... āā ʒss.
M. Q. s. ft. magma. Sig.: Dry the sore and apply thoroughly by means of a wooden spatula. Allow artificial eschar thus formed to separate spontaneously, using no dressing.

—Ricord.

Catarrh of Gall-ducts.—

℞. Ammon. iodid. ..... ʒj.
Liq. potass. arsenitis ..... f℥ss.
Tr. calumbæ ..... f℥ss.
Aq. destillat ..... f℥jss.
M. Sig.: Take a teaspoonful three times a day before meals.

—Bartholow.

Aconite is the only drug which in poisonous doses will cause numbness of, and tickling of, the first of the mucous membranes with which it comes in contact, and then of the extremities.—Hare.

Anæmia, especially when accompanied by cardiac disturbances, such as weakness and irregularity of the pulse:

℞. Iron by hydrogen,
Powdered camphor. ..... āā ʒjss.
Extract gentian ..... grs. cxxxv.
Mucilage gum Arabic. ..... q. s.
Make ninety pills. Dose: Two or three thrice daily.

—Edlefsen.

Nitro-glycerine is a heart sedative and not a stimulant.—Hare.

Chronic Rheumatic Arthritis.—Lord Anson paid £300 for the privilege of publishing the following prescription for chronic rheumatic arthritis :

℞. Sulphur ..... ℥ j.
Cream of tartar ..... ʒ j.
Rhubarb ..... ʒ iv.
Gum guiac ..... ʒ j.
Make one powder and add honey ..... ℥ xvj.

Mix well, take two tablespoonfuls in a tumbler of white wine and hot water on going to bed, and repeating the dose on getting up in the morning.

—*Louisville Medical Monthly.*

Acute Coryza.—

℞. Cocain. muriat ..... gr. vj.
Bismuth. subcarb ..... ʒ ss.
Talc ..... ʒ jss.

M. Sig : Enough to cover a silver five-cent piece insufflated into each nostril every two hours.

—Sajous.

℞. Carbolic acid ..... pt. j.
Ammonia water ..... pt. j.
Alcohol ..... pt. ij.
Distilled water ..... pt. iij.

Mix. Sig. : Gtt. 10 to be dropped on a piece of blotting-paper and inhaled for a few moments every hour.

—*Monit. Therap.*

Nasal and Faucial Catarrh.—

℞. Acid. carbol. liq ..... ♏ xxx.
Sodii biborat,
Sodii bicarb ..... āā ʒ j.
Glycerinæ ..... f ʒ iijss.
Aquæ ..... q. s. ad f ℥ iv.

M. Sig : To be used as a spray.

—Dobell.

Pruritus Cutaneus.

℞. Acid. carbolici ..... ʒ j.
Potassæ fusæ ..... ʒ ss.
Aq. dest ..... Oss.

M.

—Van Harlingen.

Marasmus.—

℞. Syrupi ferri iodidi ..... ʒ j.
Syrupi acaciæ ..... ʒ vij.
Aquæ fœniculi ..... ℥ j.

M. S. : ʒ j. t.i.d.

—Dupasquier.

Acne Rosacea.

℞. Sulphur præcip ..... ʒ j.
Calaminæ præpar ..... ʒ ij.
Zinci oxidi ..... ʒ j.
Glycerini ..... ʒ j.
Aquæ destil ..... ad ℥ iv.

M. ft. lotio.

Sig. : The lotion to be shaken, then painted on with a camel's hair brush at night.

In morning face is washed with a little warm water (no soap) and powdered over with following :

℞. Acidi borici ..... pts. x.
Talci ..... pts. xv.

M. ft. pulv.

Sig. : To be applied every morning.

—Jamieson.

Strontium Bromide in Epilepsy is less prone than potassium salt to produce acne and other disagreeable symptoms, but it has less control over the epileptic convulsion. —Wood.

Acute Bronchitis.—

℞. Carbonate of ammonia,
Salicylate of sodium ..... āā ʒ j.
Camphorated tincture of opium,
Syrup of orange flowers,
Syrup of tolu ..... āā ℥ j.
Water ..... ℥ ij.

F. S. A.—To take a dessertspoonful every three hours.

—Lewinthal.

Tonsillitis.—If obstinate, sodium salicylate should not be overlooked, as some rheumatic element is possible.—Gaillard.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

THE THROAT HOSPITAL AGAIN—THE SCHOOL BOARD'S INSULT TO DOCTORS—METRIC SYSTEM FOR THE PHARMACOPŒIA—THE LATE DR. GOODFELLOW.

London, August 17, 1895.

The Throat Hospital, in Golden Square, is again the scene of squabbling, but only a languid interest is excited by the struggles of those who seem to be defeated. A joint letter was sent to the newspapers to inform the public, that the three persons who sign it "have now entirely severed our connection with" the hospital. These three persons, who deem themselves of sufficient importance for the public to be interested in their proceedings, are : 1, the President—a nobleman and an ornamental official who probably knows little about the matter ; 2, Mr. R. Courtenay Welsh, who describes himself as "lately a member, and for nearly twelve years chairman, of the Committee of Management ;" 3, Dr. Greville MacDonald, who describes himself as "lately Dean of the Medical School, and for eight years physician." Possibly these two last are surprised that they have not found either the public or the profession at all curious as to their reasons. Far be it from me to add to their chagrin, but on the supposition that they feel aggrieved, not too great an assumption in face of their letter, and on the further supposition that they would like to know why they can obtain so little notice, I suggest, Nemesis. Let them remember their part in the great scandal of that hospital eight years ago. At that time, Mr. Welsh was chairman, and Dr. MacDonald, house surgeon, not long previously appointed. Mr. Welsh is not a medical man, but is said to be a "limb of the law." His conduct on that occasion was beneath the dignity of any pettifogging practitioner. He it was who got the late Dr. R. H. Semple to resign in order to give his day to Mackenzie's nominee, Mr. Hovell. When the staff protested and waited on the committee, Mr. Welsh was in the chair and pretended that no rule or custom of the staff could be recognized unless recorded in the minutes of the committee—which of course the staff never saw. He it was who occupied the chair when the staff unanimously resigned—no, not unanimously, Mr. Hovell remained—and when within half an hour, the committee accepted the six resignations and appointed three persons in their places. Of these three Dr. MacDonald was one. However tempting the jump from house surgeon to full physician, he could not be ignorant of what would be thought of the whole transaction, and however great may have been his satisfaction at displacing others, he ought surely to be aware that his conduct on that occasion scarcely entitles him to expect sympathy on this Nemesis.

The London School Board has made a mistake in throwing doubt on medical certificates, as to the absence of children from schools. You must know the Board does not pay for such certificates, which have been given up to now out of kindness to protect parents from the worry of unnecessary proceedings. The officials have now got the Board to sanction the appointment of medical inspectors to investigate the bona fide character of the certificates. This is regarded as an insult, and at some hospitals the physicians who had hitherto given these documents, have agreed to sign no more until the Board rescinds the obnoxious resolution on the question. If the Board persists, it will soon have no certificates to investigate. Is it reasonable that doctors should be asked to give certificates

gratuitously, and when they consent that their honesty should be impugned?

It seems to be settled now that in the coming new Pharmacopœia the metric system will be employed, but that concurrent statements will be given in the old measures. This will no doubt assist the change which will eventually become established.

Dr. Goodfellow, formerly physician to the Middlesex hospital, died lately at the age of eighty-six. He had retired from practice for a long time. In his day he did much good work, and enjoyed the respect and esteem of the profession.

SIR B. W. RICHARDSON AND SCIENTIFIC ACCURACY.

To the Editor of the Medical Record.

Sir: There is much uneasiness in the minds of the laity regarding the good or evil that may come ultimately from bicycle riding. Dependent as they are upon statistics from scientific men, it is little wonder that they are confused by the conflicting statements from what are supposed to be reliable sources. The preponderance of reports seems to be in favor of bicycling in moderation—always barring racing and hard riding. In its good effect bicycling in no way differs from any other of the out-door sports or exercises, with the additional advantage that it is less tiresome and monotonous. But now we have coming forward a certain class of supposedly scientific observers, who seem to draw all their conclusions from a racing stand-point, and judge and condemn the bicycle accordingly. They have not the fairness to state the simple fact that all exercise in excess is injurious, either directly or indirectly, to the heart, and leave the lay reader to believe that bicycling alone is the only exercise that is really a "heart-destroyer."

Sir Benjamin Ward Richardson, in a recent article in the *North American Review*, says that great injury is done to the heart by the bicycle. He makes the statement that he and some learned doctor had made the discovery that "as soon as brisk cycling is commenced the motions of the heart begin to increase." This statement is about as original as to say that as soon as the sun begins to rise the day begins to break. It leaves the impression that very few forms of exercise increase the heart's action, while we are well aware that any exercise of any kind will produce a like effect. Sir Benjamin would undoubtedly be one to advise keeping constantly in the recumbent position, simply because standing increases the rapidity of the heart's action.

He makes the statement that "rowing tells mostly on the breathing organs," presumably meaning the lungs. We should all certainly enjoy having him explain just how an increase of activity on the part of the "breathing organs" could take place without a corresponding increase in the heart's action. Increased respiration certainly means increased blood-supply, which is synonymous with saying increased heart's action. And it would perhaps interest him in a scientific way, to reconcile with his statement the fact that so large a percentage of professional and college oarsmen have been afflicted with heart disease.

He states further that "dumb-bell exercise tells mostly on the muscles, while hill-climbing and pedestrian feats affect the nervous system." Also, that "he has known the beats of the heart to rise from eighty to two hundred per minute in the first exercise of riding." This statement concerning the increased heart-rate is nothing new or surprising to the medical profession, but it gives much cause for alarm to the ordinary reader. His statements concerning dumb-bell exercise and hill-climbing, however, are so misleading that they would be either explained more fully or omitted entirely by a scientific writer. If Sir Benjamin would take an ordinarily strong but untrained man, having a normal pulse-rate of seventy-two beats per minute, and allow him to exercise simply the muscles of the arms with six- or eight-pound dumb-bells for sixty seconds, he would find at the expiration of that time that the pulse had increased to anywhere from one hundred and fifty to one hundred and sixty or seventy beats per minute. This would seem to disprove his statement or implied meaning that dumb-bells affect simply the muscular system, and also show that cycling is not alone in its action upon the heart.

He should also recall the fact that in all contests where strength and endurance are required by athletes the training to increase the strength and tone of the heart is mostly done by cross-country pedestrian and hill-climbing expeditions. But despite such exercises the nervous systems of most athletes (which must suffer inordinately according to Sir Benjamin's theory) are usually in very good condition after such long runs and climbs.

While articles such as Sir Benjamin's and others of its class have no effect upon the medical profession and scientific thinkers, still they are written for popular magazines, and in that manner reach a class of people who believe the statements made because they are supposed to give at least a truthful impression, even if only popularly scientific. One can only think of such writers that they are either thoroughly unscientific, or else so prejudiced that they are willing to sacrifice almost anything to make their prejudices seem well founded. From the article quoted above one might well infer that the writer had only recently discovered that there was an organ in the body called the heart, whose fundamental functions were as yet unknown.

New Instruments.

A NEW PERCUSSION HAMMER.

By JOHN T. GIBBONS, M.D.,

Attending Physician, St. Catharine's Hospital, the Central Throat Hospital, and Polyclinic Dispensaries, Brooklyn, N. Y.

The accompanying design of a percussion hammer may interest your readers, especially those engaged in heart and lung work. The rubber is curved so that a broader surface strikes the finger than in the hammers we have

had hitherto. It is fastened in a dome which is surmounted by a ball, which gives a requisite weight to the whole. The handle (a modification of Niemeyer's) is screwed into the ball.

1297 Bushwick Avenue.

Chloral Hydrate is the hypnotic *par excellence* when pain is not a prominent element in the case. I find it best to combine it with ammonia and strychnine, some ammonia salt, not alkaline; all alkalies are sure to bring about decomposition of chloral hydrate, thus making it utterly valueless as a medicament, especially as a hypnotic. Following is a good combination:

℞. Chloral hydrate..... gr. xx.
Ammonia bromide..... gr. xx.
Fl. ext. nux vom..... gtt. x.
Fl. ext. belladonna..... gtt. ij.

Mix. Sig.: To be taken at once and repeated in an hour or two if needed.

—Adolphus.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending August 31, 1895.

	Cases.	Deaths.
Tuberculosis	128	127
Typhoid fever	34	5
Scarlet fever	26	4
Cerebro-spinal meningitis	5	9
Measles	84	7
Diphtheria	124	21

Physiological Action of Periodical Induced Currents.—Dr. A. H. Goelet writes, enclosing the following letter from the Kidder Manufacturing Company:

"NEW YORK, August 20, 1895.

"DR. A. H. GOELET—SIR: In answer to yours of this day, would state your permission was given for winding your lengths and diameters of wire first on two stationary helices, using a No. 21 wire instead of 18 and 22; arranging it so as to give the same results. And later your permission was also granted to wind these upon one helix. Manufacturers always extend this courtesy to the profession. The coil made for Dr. Rockwell, containing 5,000 feet, was made up of Nos. 16, 21, 32, 34, 36, and 38 wires."

Dr. Goelet adds: "It will thus be seen that the coil to which Dr. Rockwell lays claim is very different from mine, which is made up of Nos. 21, 32, and 36 wire, having a total length of 7,550 feet."

A Census of Centenarians has been taken in France, and the results, which have been published, show that there are now alive in that country two hundred and thirteen persons who are over one hundred years old. Of these one hundred and forty-seven are women.

A Blood-thirsty Profession.—Deputy Surgeon-General Thornton, of England, is dreadfully frightened to find himself in the company of ghouls. In a long letter in the *Liverpool Daily Post* of August 10th he warns the public of "a serious danger which is impending over all civilized nations, and which, year by year, grows more threatening. I refer," he says, "to the danger of human vivisection, which is a direct and inevitable consequence of the rapid and sinister growth of the vivisecting spirit, and the rage for experimental research, not only in the medical profession but also among scientists generally. There are many men who, though kind and humane in the ordinary relations of life, become pitiless and remorseless when dominated by the vivisecting spirit. Their minds are filled with the ardor of research, the hope of discovery, and the expectation of riches, honors, and fame as the reward of their labors. Such men would vivisect human beings as readily as animals, if they dared, and they are only prevented from doing so now by fear of the law and public opinion." When the Deputy Surgeon-General came to, he was probably surprised to read what he had written the night before.

Medical Book-borrowers.—The editor of the *Denver Medical Times* is a victim of designing book-borrowers. He says he has lost over fifty volumes during the past year by the failure of borrowers to return his books, and he now calls a halt Denver has a medical department in the High School Library, and he warns the pestiferous borrowers to go there and leave his library alone. We extend to our esteemed contemporary the assurance of our profound commiseration.

Syphilis and the Female Genitals.—The Vienna correspondent of the *Medical Press* writes that Professor Neumann, in his paper before the Gesellschaft, reviewed the history of this dire disease as recorded by literature, and then criticised the physiological effect on conception, pregnancy, and progeny. His deductions were obtained from 6,000 cases. With respect to the recent exanthemata on the mucous membrane of the vagina, the moist papule was the characteristic form of syphilis. Clinically, this is hard to diagnose when confined to the cervix uteri, but anatomically it cannot be denied a place. In 800 cases of primary syphilis he found 51 to be located on the vaginal portio uteri, and only four times on the vagina itself. Individual diagnosis is often very difficult in multiparæ, although these appear to be the most easily affected. He has not attempted to determine the exact proportion the primaparæ stand to the multiparæ. In both the cicatrix erelong leads on to atresia and menstrual disturbances. The morbid products of syphilis, such as gumma and ulceration, are not uncommon to the female genitals. The gumma is most frequently met with at the "introitus" of the vagina, or anterior third, less seldom on the posterior or middle third. He recited a case where the gumma of the vagina resulted in a fistula with the bowel. He showed by histological specimens that recurrences frequently occur in the vagina. The ovaries and tubæ have also been assumed as the site of syphilis, but not so clearly proved. Syphilitic affections of the corpus uteri are rare, only one case standing on record as such, which may be considered as strange, seeing that metritis and endometritis with abortion is such a common result of the syphilitic poison and a fruitful source of sterility. So many hypotheses are set forth concerning the etiology that only a few may be related here. The older opinions assumed that the poison was conveyed through the ovule or spermatic fluid. The syphilitic changes that produce endo- and myo-metrium of the placenta, causing death of the ovum, is the most reasonable source of destruction. We cannot always find from a macroscopic examination of the placenta and uterus the exact cause, but when microscopically examined we find endo- and peri-arteritis of the fœtal and utero-placental vessels, as well as thrombosis with narrowing or perfect occlusion of the placental and femoral vessels, clearly demonstrating the cause of death. Myometrium is another fruitful cause. By the intervening syphilitic fœtus from the father the mother can scarcely escape the poison at parturition, as the poison can be easily taken up from the small lacerations. We know of no organ in the body where the syphilitic fluid, if freely applied, will not localize itself and recur, as we often meet with it in the neighborhood of the uterus acting as the principal source in habitual abortion. From this point of view, there are often many inexplicable cases of death of the fœtus, either before or after birth, where no trace of syphilis can be elicited in either father or mother, yet the fruit dies of this enfeeblement. On the other hand, it not infrequently occurs in pronounced tertiary syphilis, where mother and father are both syphilitic and the progeny free. Whether the cause presides in the red blood corpuscles, a diminution of hæmoglobin, or a toxine principle pure and simple, is yet to be explained by future investigation. Another hypothesis of oligæmia or pernicious anæmia of the fœtus, which may be the cause of death, cannot be denied.

Medical Politicians.—Lawyers and other laymen are not keeping up with the doctors in the political procession in some parts of France. In the department of Gers all the members of the General Council are physicians, and no non-medical man could well have been chosen at the last election, for every candidate was a doctor.

Furuncles.—A strong solution of chloral hydrate in glycerine and water frequently applied, it is said will abort furuncles.

THIRD REPORT ON ELIMINATIVE AND ANTISEPTIC TREATMENT OF TYPHOID FEVER.

BY W. B. THISTLE, M.D., L.R.C.P. LOND.

ASSISTANT DEMONSTRATOR OF ANATOMY, UNIVERSITY OF TORONTO; LECTURER ON DISEASES OF CHILDREN, WOMAN'S MEDICAL COLLEGE; PHYSICIAN TO VICTORIA HOSPITAL FOR SICK CHILDREN.

REGARDING the immense amount of energy and effort expended in the study of disease-producing fungi or bacteria, it would be but mere commonplace to say that all the accumulated knowledge, the result of such expenditure, can be of little worth apart from gratification of scientific curiosity, until it can be brought to bear directly upon the treatment of disease due to these organisms. Assuredly, too, the more accurate and comprehensive a knowledge of bacteria is gained, the more clearly outlined become the indications for treatment. In order to have this harmony between pathology and treatment, it is necessary, in the first instance, to be as fully informed as possible concerning the invading micro-organism, and how and why it is able to bring about the tissue changes and clinical symptoms peculiar to it; and, in the second, to remember and constantly to strive to apply that knowlege when the diseased condition appears.

With special reference to typhoid infection it occurred to me, some three years ago, that the treatment advised in current text-books, and that almost universally taught, did not follow at all closely as a logical sequence on what had been ascertained concerning the nature and pathology of the disease, that there was in fact a lack of harmony between pathology and treatment. Accordingly, I attempted a plan of treatment which seemed to me to embody the application of valuable facts relating to the infective germ, and the way in which it brought about disturbance and destruction in the human body. Two years ago I published this plan of treatment in the *Canadian Practitioner*, April, 1893, under the title of "Eliminative and Antiseptic Treatment of Typhoid," and with it all the cases so treated. In 1894 a second paper under the same heading appeared in the MEDICAL RECORD of March 10th. To this second paper I appended an analysis of forty consecutive cases without fatality, and running a course unusually short and unusually free from distressing symptoms, and from what have been spoken of as the accidents of the disease.

I now beg to make a third report, and in doing so I shall in no way alter the original title, for nothing to my mind would so clearly indicate the principles of treatment as the two words "Eliminative" and "Antiseptic." I shall, also, still adhere to what seemed to me on the former occasions the correct way to approach a discussion of this kind, and first gather together, as completely and as concisely as I may, what has up to date been determined by bacteriologists and pathologists concerning the germ itself, and also the relation which it bears to the lesions and symptoms of the disease. By so doing it becomes easier to appreciate consistency or want of consistency in the principles of treatment which I shall have to bring forward, as well as in those which are generally accepted and taught.

It is, of course, past question that enteric fever is the result of bacterial infection. So far, all are agreed, but when it comes to giving credit to one particular variety, there is by no means a like unanimity. There are those who attribute everything to Eberth's bacillus, while there are many observers who are of the opinion that other bacilli, as well, are responsible for part at least of the disturbance. The bacillus coli communis, particularly, is by many considered to produce much of the toxæmia. Others, again, urge that Eberth's bacillus is simply a modified form of common colon bacillus. The great difficulty in distinguishing Eberth's bacillus from the bacillus coli communis, perhaps, accounts for these varied views. There are, however, many apparently sufficient reasons for believing that common bacillus of the intestine is responsible for a portion of the disorder, even though Eberth's bacillus be recognized as the primary and chief aggressor in the disease. There is the primary fact, with reference to bacillus coli communis, that it is capable of producing toxæmia even to a fatal degree. Treves,[1] in his paper on peritonitis, describes the condition, when associated with intestinal disease and injury, as one of poisoning from escape of these bacteria from the injured or opened intestine, followed by rapid spread over peritoneal surface, with correspondingly rapid absorption of the toxic substance to which they give rise. It may, then, be taken as proven that the bacillus coli communis is poisonous. Under ordinary circumstances the quantity absorbed is not sufficiently great to give rise to symptoms. It is more likely, though, that immunity from this constant poison is due to the functional activity of the liver in intercepting and destroying these harmful substances.[2] Treves,[3] also, expresses the opinion that, under certain circumstances, the common bacillus of the intestine becomes more virulent, which is quite in keeping with what has been determined in experimental growths of other forms of bacteria. It is maintained by others that this increase in virulence occurs when it is associated with Eberth's bacillus. However, looking at the condition which prevails, say in the first week of typhoid, it becomes evident that many forms of bacillus are to be found throughout the intestinal canal. Owing to lack of secretion, food materials are not digested and absorbed, but the mass remains to be broken up by the ordinary germs of putrefaction, absorption of toxic products of course taking place. It is only necessary to imagine this process repeated and continued, to be convinced that many forms of bacteria are present in addition to Eberth's bacillus and the bacillus coli communis, and that some portion of toxæmia must be attributed to these putrefactive or unclassified germs. Given Eberth's bacillus as the primary cause, it requires no argument to prove that other forms must play a part in the production of symptoms.

We have only to recall the manner in which bacteria bring about disturbance, by virtue of the toxic substance which they produce, to perceive clearly that the condition in typhoid is one of continuous intoxication. The primary and chief source of the poison is the alimentary canal, although it should not be forgotten that some portion of toxæmia must be attributed

[1] British Medical Journal, January, 1894.
[2] Lauder Brunton: Disorders of Digestion.
[3] Treves: British Medical Journal, January, 1894.

to poison elaborated by bacteria which have been carried from the intestine and deposited in the various tissues of the body, notably in tissues most directly connected with the alimentary canal, *e.g.*, lymphatic nodes of intestine and mesentery.

I am fond of comparing the prolonged poisoning of typhoid to the commonest intoxication we are familiar with, *e.g.*, alcoholic. Typho-toxin and alcohol are each the result of bacterial action, under certain conditions. One process takes place within the body, the other without. Each poison has in the main its characteristic train of symptoms. These symptoms are the physiological effects, and from a survey of these signs we can estimate approximately the degree of poisoning, always remembering that, as with alcoholic poisoning so with the toxæmia of typhoid, individual peculiarity may play a part, that certain conditions may increase susceptibility, while certain other conditions may have a directly contrary effect. It must be remembered, too, that in neither case are we always dealing with the pure drug. With alcoholic poisoning must be included frequently poisonous effects arising from introduction of these substances usually separated and removed. Making allowance, then, for these conditions and peculiarities, it remains true that, just as we judge of the degree of intoxication from the appearance and actions of the drunken man, so in the case of typhoid we can read in the symptoms the amount of toxin in the system.

With reference to the local effects of typhoid poison we are not able to estimate so accurately their degree. We have, however, a few valuable facts concerning the effects of typhoid toxin: 1. That it will irritate tissue-cells and produce swelling, congestion, and infiltrations of the part. 2. That, if it becomes concentrated to a sufficient degree, the irritation is replaced by complete destruction or necrosis. 3. That necrosis may be brought about, not so much as a result of concentration of poison, but owing to long continuance of contact[1] (Sims Woodhead). It is only in the case of the grosser destruction of tissue, *e.g.*, in the intestinal lymphatics, that this local or "caustic" effect can be considered quite apart from those derangements of function which depend largely upon the local effect widely distributed, *e.g.*, rapid tissue waste or increased rate of molecular death from wide-spread irritation. It is, then, safe to assume the local effect whenever the general symptoms are present. To state it concisely, there is in typhoid fever infection of the body by bacterial growth, which brings about a condition analogous to fermentation, with the production of a chemical substance, "typho-toxin," which when diffused through the body gives rise to general symptoms, and where concentrated, to irritation or complete destruction of tissue.

Facts to be carefully noted are: 1. That general symptoms are increased or diminished according to the amount of poison in the body, or dosage. 2. That the extent or degree of local lesion is determined by the degree of concentration of the poison and the duration of contact.[2] Fenwick and Bokenham have succeeded in isolating an albumose from the spleens of those who had died in the third week of typhoid fever. Experimenting with this substance on animals, they found that if it be injected in quantities exceeding 0.02 gramme per kilo of body-weight, there is invariably elevation of temperature and anorexia. The more the dose is increased above 0.02 gramme per kilo, within certain limits, the higher the temperature. If injections above this quantity are given on alternate days, there is persistent elevation of temperature with anorexia and rapid diminution of body-weight.

Leaving the consideration of what has been determined concerning the poison of typhoid and its action on the organism, let us turn to consideration of the way in which infection takes place, and how the fungi become established in the human body. Whether we say infection is due to Eberth's bacteria or to a modified colon bacillus, it most assuredly comes from without. For the purpose of this paper, it is taken in with contaminated water, is not destroyed in the stomach, and takes on active growth in the small intestine. Very shortly large numbers of intestinal lymphatic nodes become swollen and congested as the result of the invasion of bacilli which have come from the intestinal contents. Shortly, the mesenteric glands become affected in the same way, and after a time bacilli may be found in clusters in many parts of the body. In a former paper I ascribed the apparently selective tendency of these organisms for the solitary glands as due simply to the anatomical arrangement by which each lymph-node became as it were a small reservoir, into which bacteria and poison were conveyed by the numerous lymph-ducts which drain the surrounding area of intestinal surface.

This "hiving" or concentration makes it clear why the intestinal lymph-nodes almost invariably present a marked degree of local change. There are those who maintain that now, although there may be and usually is infection of lymphatic glands for several feet, as well as of other tissues, the infective micro-organisms are no longer to be found in the intestinal contents. But after some time, about the eighth[1] or ninth day and during the remainder of the attack, they may be found in the bowel discharges.

When one stops to consider it, this seems an improbable thing, for in the first instance the contents of the intestine must have been favorable for growth at the time the intestinal lymphatic nodes and the body generally became infected. Then, in the second, it is necessary, in order to have simultaneous invasion of many glands scattered over several feet of intestine, to presuppose that the bacilli taken in with the glass of impure water must have multiplied to some considerable extent. Now, how comes it that after this wide-spread infection of the intestinal glands the bacilli are no longer able to flourish in the intestinal contents? They most assuredly have been able to exist and flourish there, and, according to those who hold the view I have mentioned, after this disappearance they return again and once more find the conditions suitable. From this time, as early as the eighth or ninth day (Klein), until the termination of the disease, they continue in the intestine.

I confess that this theory of presence in the intestinal contents, followed by disappearance, and again by reappearance, is hard to understand. To those who urge that it is exceedingly difficult to distinguish Eberth's specific bacillus from certain forms of common colon bacilli; or to those who maintain that typhoid is due to a virulent form of colon bacilli, this difficulty does not present itself. According to them the specific germs may be present in the intestine throughout the first days of the active disease, as well as during the period coincident with infection of the intestinal lymphatic nodes, and that period remaining after the first ten days or fortnight.

Leaving these diverse views, and taking into consideration the facts of the case only whether it is decided to have a specific Eberth's bacillus or modified colon bacillus, or whatever may be decided as to name—it becomes clear that the infective germ must have been present in the lumen of the intestine in order to have infected the intestinal glands, and there in very considerable quantity, in order to have produced infection simultaneously in so many glands scattered over so great an extent of surface.

It is also beyond a doubt that the specific germ is present in the discharges during a portion of the period which follows infection of the intestinal glands, because

[1] Woodhead: Bacteria and Their Products.
[2] British Medical Journal, April 13, 1895, p. 801.

[1] Klein: British Medical Journal, October 13, 1894; and Hirschfeld: British Medical Journal, April 20, 1895, p. 869.

whole epidemics have been traced to contamination from active cases. Besides, there is no disagreement concerning their presence during the later period. Now, what reason is there for the assumption that the intestinal contents possess immunity during this intervening period?

Then, are we to assume that migration of bacilli from the intestinal contents to the intestinal lymphatic glands is fully completed before any constitutional symptoms arise? Such a theory is manifestly unreasonable, yet unless we maintain it absolutely we must admit that the infectious germs which give rise to the disease form part of the intestinal contents in the early stage of the disease. In other words, the process of invasion of the glands is coincident with the earlier symptoms of toxæmia.

When all are agreed that it is impossible, from a morphological stand-point only, to distinguish a specific typhoid germ from the colon bacilli which are always present, and when many bacteriologists maintain that there are no specific germs apart from the modified colon bacillus, it does seem unnecessary to assume this period of absence, leaving out of consideration altogether the manifest absurdity which I have just shown this theory to involve.

I have devoted some space to this question, because since I first advocated active treatment of typhoid, objections have been raised on the ground that in the early stage of the disease no specific bacteria are to be found in the intestine.

Let us, now, turn to the question of treatment of the condition arising from the infective process briefly described above, and in so doing adopt the plan indicated in the beginning of this paper, to arrive at the treatment by applying the knowledge possessed of the infective germ, and all relating to it. It can scarcely be said that this has been the plan adopted in arriving at the treatment of the past. Until recently treatment was nothing. In many countries "let alone" is still the vogue.

In my first paper I stated that I believed all the indications furnished by a study of the morbid process were met by the adoption of a plan of treatment embracing three distinct heads or principles: Elimination, antisepsis, and dilution. I still adhere to that belief. Elimination is accomplished by free and continuous purgation, as well as by the flushing action of large quantities of water on kidneys and bowels. By the use of purgative medicines the infective process is disturbed in several ways: 1. Bacilli are carried out of the intestine together with the toxic substances produced by them. 2. Poison held in solution by the body fluids escapes with the free secretion into the intestine: and besides, at frequent intervals a quantity of what, in this instance, must be extremely toxic bile, is swept away instead of continuing in the circuit from the liver to the intestine and back again. If constantly relieved in this way the liver can more frequently perform its *rôle*[1] of standing guard and intercepting toxic substances which would otherwise reach the general circulation. 3. Infection of intestinal glands is limited, or, in other words, the source of supply from which bacilli and poison are carried from the intestine is cut off. That is, just as you can and do limit the dose of poison received by the system generally, so do you limit the local dosage and consequent injury of the intestinal glands by the same means. This surely requires no argument, it is evident, if only one stops to recall the manner in which infection takes place. In the one case, lessened dose means milder symptoms, and in the other the smaller the local dose the less severe the local lesion.

Concerning toxin already absorbed and in contact with the tissues, held in solution by the body fluids, some portion of it must be removed with the secretion poured into the intestine, when stimulated by purgative medicines, as well as that drained off through the kidneys. There is nothing unusual in such a claim. We have many examples of removal of poisonous material from the body by similar procedure.

By repeating this process it certainly tends to prevent a dangerous accumulation of toxin in the system, and at the same time prevents, or tends to prevent, local lesion in the intestine from becoming sufficiently great to destroy a vessel, or extend entirely through the intestinal wall. It must not be forgotten that tissue resistance is increased just as the tissues are freed from the effect of the poison. Hence the tissue-cells are in this way rendered more capable of resisting and destroying the bacilli already present in them. It is obvious, too, in order to escape harm, the earlier elimination is brought about and the more constantly it is secured, the better, whether with reference to general symptoms or local lesion. In many instances, I believe, brisk purgation in the early stage carries out so much of the culture and relieves the tissue to so great an extent that the remaining bacilli are destroyed by the liberated tissue and the fever is aborted.

When this is not accomplished, or when the case is not seen early, then purgation must be prompt and energetic enough to relieve dangerous conditions, and continuous enough to keep the dose of poison below a harmful point, if possible, until such time as immunity is reached. In judging of the amount of poison present, attention should not be exclusively directed to one or two symptoms, but the entire list of symptoms should be considered.

Coming now to the second feature in treatment, that is, attempting to destroy micro-organisms by antiseptics, there can scarcely be doubt about the possibility of doing this to some degree. It is quite possible to completely deodorize the contents of the intestine by means of salol or salicylate of bismuth, and, no doubt, by other agents, as anyone can demonstrate. But to be efficient, antiseptics should be used in association with purgatives for the following reasons:

1. Just as it is easier to approximately sterilize an abscess-cavity after first having emptied it, so is it to derive benefit from intestinal antiseptics if the intestine be first cleared of its contents.

2. Intestinal antiseptics, while lessening the production of poison by destroying bacilli, yet could have no possible effect on the poison already in the intestine, but in many instances might themselves add to the toxins present.

3. Much larger quantities of antiseptics can be used without poisonous symptoms arising, if, at the same time, elimination by the bowels is continuously maintained. Any benefit derived from an antiseptic is obtained at once, and if it is speedily cleared away much which would otherwise be absorbed escapes with the contents of the bowels.

The remaining factor in treatment is clearly indicated, for the local effect of the poison depends upon its degree of concentration, as well as upon duration of contact.

Injection of large quantities of fluid is a necessary adjunct to elimination. Fluid drained off, continuously carrying with it the poisonous material it contains, must be replaced. If this were not done, the tissues would suffer from lack of fluid and the toxin remaining would assume a more concentrated, and therefore a more active, form. It might be well, at this point, to consider elimination by purgation in its relation to certain accidents of the disease, *i.e.*, hemorrhage and perforation. I do not propose to enter into the question at length, but shall content myself by pointing out that, if it is true that the local lesion is proportionate to the local dosage and duration of contact, and if it is true that the toxin and bacilli, which would otherwise reach the lymphatic glands, can be carried out by purgation, then it must be that elimina-

[1] Bouchard: Auto-intoxication in Disease.

tion by purgation tends to lessen the occurrence of both hemorrhage and perforation.

In the late cases the indications are the same. If a vessel is already necrosed, hemorrhage is unavoidable; if not already necrosed, the way to prevent it becoming so is by removing the poison. With reference to this point I beg to refer to the paper in the *Canadian Practitioner* of April, 1893, or to the MEDICAL RECORD of March 10, 1894, where I have discussed this question at length. I still maintain the same conclusion, that purgation at no time causes perforation or hemorrhage, but at all times tends to prevent its occurrence. Misconception regarding this matter was the great barrier which interposed whenever an attempt was made to follow in treatment the indications furnished by study of the morbid process. So great was the dread of these two accidents that the fact that the great majority of fatalities were due, not to hemorrhage and perforation, but to toxæmia, was lost sight of. A study of the cases I have to report with reference to this point, will, I believe, convince the most sceptical that formerly a misconception did exist.

So much for meeting the indications furnished by consideration of what has been determined concerning micro organisms on paper or in theory. How does it work out in actual practice? Precisely as it does in theory.

I have to report 172 cases with a mortality of five, or three per cent. No cases were excluded, late cases are taken as well as early. Forty-four of these were my own patients. Forty-one cases were treated at the Toronto General Hospital, to a considerable extent under my own direction, and in every instance under my observation. The remaining 87 cases were furnished me by several medical friends, with two exceptions resident in Toronto.

I have excluded none from my list, whether coming under eliminative treatment early or late, provided only that the treatment had been fairly carried out from that time. Concerning the cases received from others, I can only speak in general terms. All these cases were reported as having done well, with two exceptions, and the treatment gave results such as I have indicated in the papers published. One case died from hemorrhage and one from pneumonia during early convalescence. The hemorrhage case had been ill in the country while nursing a case of typhoid; returned to the city, and after two weeks' illness was again taken to the country. When seen she was comatose, had tympanites, and temperature of 104° F. Given saline in drachm doses every four hours, and shortly the temperature fell, tympanites disappeared, and consciousness returned. On the third day, at 12 A.M., she had a slight hemorrhage and the saline was discontinued. Next day, at 5 P.M., she had a severe hemorrhage and died at once.

The case of pneumonia occurred in an alcoholic, and in my opinion it is doubtful whether he ever had typhoid. However, I have included his case in my list. In two other cases hemorrhage occurred, but treatment was persevered in with favorable results.

Coming now to my own cases, forty-four in number. I had one death from pneumonia, following a very severe attack, in a boy nine years of age. In this case, too, there was slight hemorrhage, which I thought might come from the rectal veins, as it was small and bright in color. The autopsy showed a remarkable condition of the intestine. Although death took place in the fourth week, two minute ulcers only were found in the ileum, but the intestinal glands throughout were swollen.

The forty-one hospital cases gave two deaths. One from hemorrhage, where the autopsy showed the presence of ulcers from the ileum as far down as the sigmoid flexure. She had been in the hospital eight days when death occurred. This case presented symptoms of severe infection, high temperature, distention, and a dusky expression. She did well until the hemorrhage occurred. This was slight at first. The purgatives were discontinued and opium given until termination fatally from extensive hemorrhage.

The second fatal case occurred from hemorrhage from the stomach and nose with general purpura, hemorrhage in every part of the body. Autopsy showed a large number of ulcers, covered with black, dry sloughs. The patient died on the fourth day in hospital. These five cases make up the entire list of fatalities. Two died from pneumonia, after recovering from severe attacks of typhoid.

The two fatal hemorrhages occurred in cases coming under observation, certainly, in the third week of active illness. Both cases gave indications of profound and dangerous toxæmia, which disappeared as soon as elimination was secured.

Analysis of one hundred and seventy-two cases. Mortality of three per cent. No death from toxæmia. No perforation. Hemorrhage in eight cases, including the two fatal cases. My own single case of hemorrhage was so slight that I attributed it to rectal engorgement. In all the cases where I had opportunity of observing, except the two fatal cases, the amount lost was small.

Tympanites never developed in my own or hospital cases during treatment, and where present at first invariably disappeared as soon as elimination was freely secured. Delirium practically unknown after the first days, and I cannot recall a single instance where it was present after treatment became established.

Out of sixty-four charts in my possession, fifty-eight show that the highest temperature reached was in the first three days. That is, the temperature inclined toward normal as soon as elimination was secured. In many instances the chart shows decline in temperature as regular as a flight of stairs, *e.g.*, charts Nos. 1, 2, and 3.

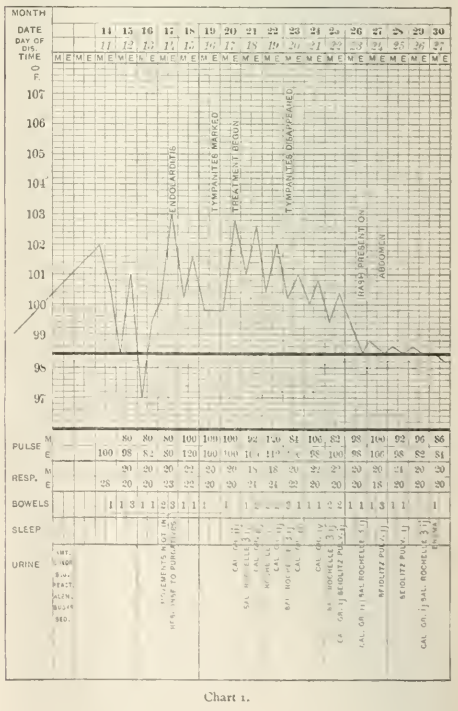

Chart 1.

The pulse, contrary to opinion often expressed, improves with the general symptoms, and it is no uncommon thing to have a pulse between seventy and eighty, strong and regular, after two weeks of continuous purgation. For example, average movements five

per day for eleven days, pulse eighty; average daily movements four for eighteen days, pulse seventy-eight; average movements per day five for twelve days, pulse sixty-eight.

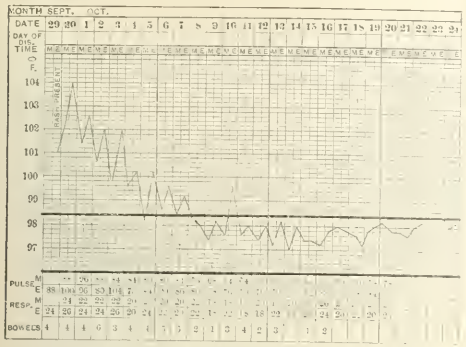

Chart 2.

Diarrhœa, in my own cases, never required controlling treatment. The difficulty was rather the other way. In many instances it is not an easy matter to secure sufficiently free movement, and different purgatives and expedients must be resorted to. Sponging as routine treatment twice daily, but in my own cases never required for reduction of temperature. Lately, many who are warm advocates of the cold bath or Brant treatment, have arrived at an explanation of its action. It promotes elimination[1] of toxin by the urine, increasing the toxidity of the urine five times. Very good; but why confine elimination to the kidneys? Bouchard has shown that in health the bile discharged into the intestine contains just six times the amount of toxin that is discharged with the urine. In the event of unusually toxic processes occurring in the intestine it is fair to conclude that the toxidity of the bile would be very greatly increased. If increased elimination of toxin is the great desideratum, one need not look far for a more direct method than that of immersing the sick man many times a day in a tub or a bed full of cold water. Besides, he is not likely to cry so loudly or beg so pitifully to be allowed to escape if elimination is promoted in some other way.

In short, under this method of treatment the striking feature is the absence or speedy disappearance, in practically every case, of the classical group of symptoms, delirium or coma, tympanites, subsultus, and the extremely foul condition of the mouth and tongue. The two following cases are examples of speedy improvement:

Case I.—Alice G——, aged twenty-four, under Dr. J. E. Graham, was the first case treated in this way in the Toronto General Hospital, Dr. Graham kindly allowing me to supervise the treatment. When the treatment began she had already been seven days in the hospital. Had been given no purgative medicine whatever. She was dusky and drowsy, had decided

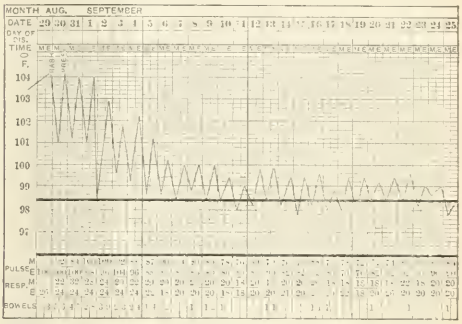

Chart 3.

tympanites and muscular tremor. There was a well-marked pericardial friction rub, also an aortic regurgitant and mitral systolic murmur, all appearing within a few days. Treatment began on the 17th, and free elimination by daily doses of calomel and Rochelle salts secured. Improvement every day. Tympanites completely gone on the 20th, and on the 24th the temperature became normal and continued so. At the same time a perfectly typical rash was present (Chart 1).

Case II.—Also a patient of Dr. J. E. Graham in the General Hospital. I was asked to see him in the absence of Dr. Graham. He had been ill for two weeks

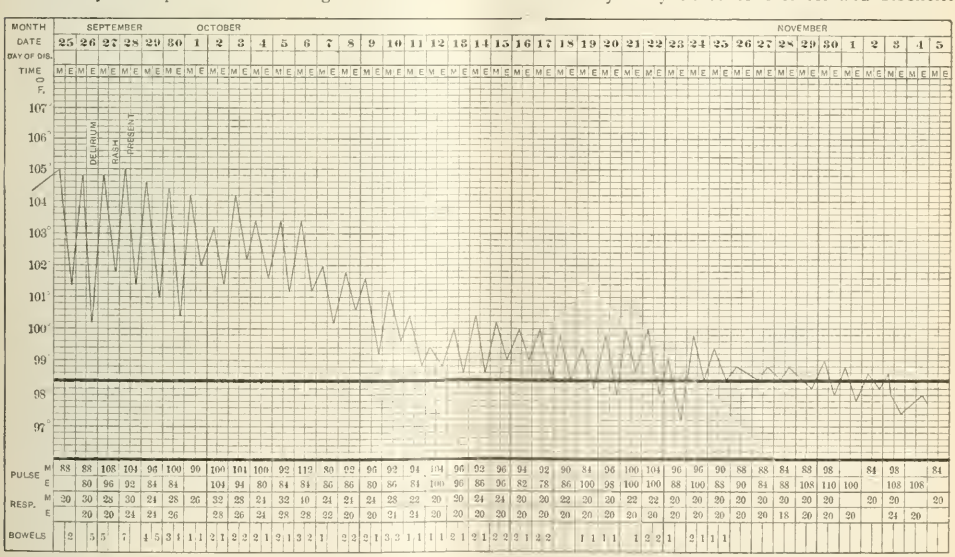

Chart 4.

[1] Burr: Chicago Medical Recorder, October, 1894, p. 229.

and had been in the hospital five days. Temperature, 104.2° F., when seen on the evening of the fifth day (Thursday). At the time of my visit he was profoundly unconscious, with greatly distended abdomen, stertorous and rattling breathing, jaw fallen, tongue dry, tremulous and spasmodic conditions of muscles, subsultus, and picking at the bedclothes. In fact he seemed to be in extremis. I advised magnesia sulphate, half an ounce at once, and continued in drachm doses every hour, and plenty of fluid. In addition, in order to hold him until toxæmia should lessen, strychnine and whiskey were given at intervals. This was on Thursday evening, the 16th, and on Saturday morning he was quite conscious. Purgatives were continued vigorously. Condition continued to improve, and on the 22d the temperature became normal; subsequently it rose slightly, and again became normal on the 27th, to continue so.

In this case I am convinced the patient would have died in a very short time if the toxæmia had not been quickly lessened.

Charts 2, 3, and 4 are quite characteristic, and show the number of bowel movements daily. I have frequently been asked how much purgative should be given in a day. One can have no fixed rule. The idea is to give enough to secure elimination, and the amount required is a matter of experiment in each case. Usually three or four grains of calomel in divided half-grain doses, followed by a saline in three or four hours, will result in free elimination. If not, compound cathartic pill No. 2, followed by sulphate of magnesia or other saline, or else sulphate of magnesia alone in repeated doses. At any rate secure elimination quickly, it matters little how it is done. In many cases days are lost. The dose ordered to-day fails to purge. Next day another is ordered, still without result, no provision having been made in the event of the medicine ordered not being sufficient. In this way several days may go by, and while the patient may be taking purgative medicine he is certainly not receiving eliminative treatment. Indeed, I have known this condition of things to exist during an entire illness. Of course, treatment after that fashion must be due either to carelessness, or failure to grasp the principle in eliminative treatment.

THE AUSTRALIAN, OR O'HARA, OPERATION FOR THE RADICAL CURE OF HERNIA.

By THOMAS H. MANLEY, M.D.,

NEW YORK.

In the spring of 1894, while making a tour through the London hospitals, it was my privilege to witness many surgical operations that I never before had seen, and a few that I had not even heard of.

The great attraction which British surgery had for me was the generally humane character of the aims which inspire the operator, and the pronounced conservatism which one sees extended to all cases, with few exceptions.

It was my purpose, particularly, to determine, as far as possible, just what the position of hernial surgery was, in those cases of non-strangulated variety; and endeavor, if possible, to gather some information of the details in technique of operating that might enable us to give our patient a better assurance of permanence of cure after operation than has been before possible. Happily, in this respect, my hopes were realized.

One afternoon, while in attendance on a clinic held by Mr. Golding Bird, a case of hernia was brought in for operation. My surprise was great when I saw him commence and go through an operation, of which I had no knowledge before, though of late years I had made a searching examination into all available literature on hernial operations, the ancient as well as the modern. The professor described the various steps of the operation, performed it with great skill and ease, and highly commended it, but failed to mention the name of its originator or its history.

My impression of the operation was so favorable that, as soon after my return home as a case of reducible inguinal hernia came under my care, this particular operation was employed, and since the latter part of April, 1894, twenty one cases have been so treated by me, and in no single instance has there been a relapse, as far as I can learn. I have since learned that Henry O'Hara, M.R.C., S.I. senior surgeon to the Albert Hospital, Melbourne, Australia, first devised it. At the late meeting of the National Association of Railway Surgeons, at Chicago, on the invitation of Professor John B. Murphy, a surgical clinic was held by me in Cook County Hospital, on which occasion I was enabled to perform the O'Hara, or Australian, operation for the radical cure of reducible hernia, and demonstrated the various steps of its technique. Its simplicity and *rationale* so pleased those who saw it that a large number have since urgently requested me to publish a description of the operation, and so illustrate it that they might the better understand it. To fulfil this purpose, and, besides, recommend to the profession what has impressed me as the most desirable, safest, and most durable of all surgical cures of hernia, these few notes are submitted.

In the beginning it is necessary that we have a correct understanding of the precise etiological elements which enter into a hernia, in order that we may the better appreciate how far we may hope to deal with this infirmity by surgical measures; for it may be well to confess at the outset that there are several types of hernia quite beyond our power to cure.

The three anatomical elements which enter into the development of hernia are: 1st, Parietal; 2d, visceral; and 3d, mesenteric. Besides these, there are many other determining factors. The parietal only will be considered here, and only so far as may be necessary to discuss the special plan under consideration; for in that class of cases only in which the faulty development of structure is lodged in the walls, involving the canals of emergence, can we hope for or promise permanent results.

M. Paul Ségond, in his classical work on hernia,[1] was disposed to take a pessimistic view of modern surgical operations for hernia; because he believed there was a certain mortality attending them. Of late, however, he has changed his opinion. In properly selected reducible herniæ, treated skilfully by the method here described, there should be no danger to life at all.

The technique embraced in the O'Hara operation combines some of the principles of the more ancient methods of Gerdy, Watzer, and Valette, with the more modern of Reisel, Macewen, and McBurney, *i.e.*, invagination with obliteration of the lumen of the sac, to which is superadded the more modern procedure of the open incision.

It radically differs from all other modern operations inasmuch as it leaves the abdominal walls intact, the inguinal canal open, and the sac undisturbed in the scrotum. This is wherein its great strength lies; for in all cases, after treatment by this plan, we can give our patient an assurance that, if we should fail to accomplish a permanent cure, we still do not leave him in a state much worse than though nothing had been done, as is the case with many other current operations.

As will be seen, the ideal cases of herniæ which are the most appropriate for the O'Hara operation are the indirect complete inguinal in the male, although with some slight modification it may be utilized with advantage in the femoral or inguinal of the female.

In order to derive the most satisfactory results with this operation, we should exercise discretion in selecting our cases; taking due care to exclude those which are very chronic, or have undergone extensive structural changes.

Hernial operations, in reducible cases, are under-

[1] Traitement Chirurg. des Hernies, par M. Paul Segond.

taken chiefly for three reasons: 1, To obliterate a deformity-cosmetic purpose; 2, to place a hernia in such a position that it may be more safely and comfortably supported by a truss; and, 3, to secure a definite cure. This operation, as far as my experience goes, fulfils the two latter in a larger measure than any other, and for its cosmetic results is equalled by none yet undertaken by the open incision.

The Various Types of Hernia for which the Australian Method is Best Adapted.—It goes without saying that there are various ruptures that should never be operated on except in the presence of impending, or actual, strangulation. There are many others of such varied anatomical elements that no definite lines can be followed in dealing with them by operative methods; and thus it is that with the scheme here described there are certain types in which we must deviate from our regular course after an operation is begun.

Complete, Indirect, Inguinal Hernia in the Male.—The most common variety of hernia, viz., the complete, indirect, inguinal, is that most suitable for the O'Hara operation, inasmuch as in this we have the sac well down in the scrotum, and are able to separate the neck or stalk as it emerges through the external ring.

In the female, when the viscera make their way out through, or by, the canal of Nuck into the labium majus, we may succeed equally well. It is well to remember, however, in this, which is an unusual form of hernia in women, that the extrusion commonly consists of some of the organs of generation, and that the inguinal canal with the female is very short and rudimentary.

Congenital Inguinal Hernia.—With cases of congenital inguinal hernia, as there is an absence of a free, peritoneal investment, and hence no sac, we may strip the fascia propria off the elements of the cord, and invaginate it in such a manner as to quite completely obturate the inner ring.

Bubonocele.—Bubonocele consists of a hernial arrest within the inguinal canal between the rings; or the apex of the sac may extend a short distance just outside the external ring. In genuine bubonoceles the anterior wall of the inguinal canal must be opened, when we will be obliged to invaginate the peritoneal pouch entire. When any part of the sac protrudes through the external ring, we may easily draw it down and free it from the cord, when it may be turned on itself and sent entire through the internal ring.

Femoral Hernia.—In femoral hernia of recent development we may utilize this method with advantage; though as all surgeons well know, owing to the intimate contact of the fascia propria with the great blood-trunks, the utmost caution must be observed in the process of isolation, inversion, and anchoring the neck of the sac. If we keep close to the inner border of the falciform process and send our carrying-needle through the conjoined tendon, or Haselbach's triangle, we will avoid all danger of vascular damage.

Age.—Seven of my cases were in children under five. In all this class, when they are over measles and whooping-cough and have ruptures which are incoercible, the earlier they are treated the better. These little ones suffer but very slightly from the operation, and can be scarcely restrained from running about after the first few days succeeding the operation.

Period of Convalescence.—One of the greatest advantages of this operation is the very brief convalescence.

As there has been no shock to the system, no extensive division of tissues with large breaches in the soft parts to close in, there is no pyrexia, no constitutional disturbance; and as a rule, with adults, it is my practice not to confine them in bed beyond nine or ten days. Children are allowed to be up after a week, but a spica-bandage is worn for six weeks later, when all supports are cast aside. With adults, as the reparative power of the tissue is not so active, it usually requires about a fortnight for complete union.

Technique of Operation.—In order to endeavor to render the written description of this operation more comprehensive, I have had struck off the few diagrammatic sketches here inserted, although, as there is a great diversity in the pathological changes of the tissues which we encounter, and the extent in the alteration and changed relations of the anatomical structures, no description by pictorial illustration, however perfect, will convey more than the most elementary outlines for an operator.

The Extent and Site of the Division of the Tissues.—In uncomplicated cases of reducible, indirect, inguinal hernia, we commence by making two incisions. The first, or inguinal incision, is made down on the neck of the sac as it emerges through the external ring. A two-inch incision carried downward over the long axis of the protrusion in the direction of the scrotum, or labium, according to sex, will give us ample space to reach the peritoneal envelope, completely detach it from the spermatic cord, lift it out of the opening, draw it well downward, transfix, ligate, divide, and invaginate it.

The position and extent of this incision must be modified according to the volume and site of the hernial descent.

The precise and exact manipulation of this incision, and what it exposes, constitutes the key to the operation.

In order to proceed with rapidity and safety it is not only necessary that we are familiar with the normal elements of the spermatic cord, but we must also fully understand the extensive alteration in structure which we may be prepared to meet in the generality of cases. In fully developed scrotal hernia of moderate volume our course is clear. The sac is adherent to the connective tissues of the scrotum, the infundibular process of the cord is quite free, therefore we readily expose and lift the neck out through the opening.

It will be remembered, however, that in some varieties of inguinal hernia the sac is quite free and elastic, following closely on the contained viscera in reduction; so that when we open down over the track, which but a moment before it occupied, we find nothing except the spermatic structures, for it has ascended to the internal ring, or at any rate it is within the canal,

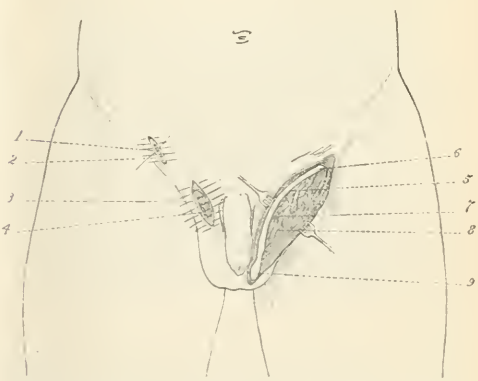

FIG. 1.—Showing on Right Side Relative Position of Intestine, etc., with Complicated Hernia on the Left. 1, Divided layers of coverings, iliac incision; 2, free loops of ligature; 3, inguinal incision; 4, neck of sac; 5, vas deferens; 6, spermatic nerve; 7, spermatic artery; 8, pampiniform plexus; 9, testis.

out of sight. In others, though just before operation the rupture comes down well into the scrotum on incision, after reduction we will find in some cases that the sac is so far pulled up the inguinal canal that only its tip emerges through the external ring (Fig. 1).

In another, not uncommon, form we will find no fascia propria of the cord.

The peritoneal pouch (Fig. 1) comes down not on our side, under or over it, but directly through its various strands, which cling to its walls with such tenacity that a delicate dissection may be necessary to free them before the sac is divided. After we have reached this and completely insolated it, our next step will be to be positively assured that it is empty of the viscera. If these are adherent to the internal surface we should open the sac and liberate them before division. Now we will pass the index-finger up the inguinal canal and free the spermatic cord from the neck of the sac as far up as the internal ring. While the finger is in the canal the lip is gently pressed against the internal ring until this is somewhat dilated. We are now ready to make the second or iliac incision, which should be situated half an inch posterior and above the upper margin of the inner aperture.

This incision should not be more than one inch in length and should extend down to, but not through, the fascia transversalis. At this site we escape the internal epigastric artery and have nothing to fear from hemorrhage. The index-finger is kept in the canal, pressing the integuments outward and maintaining a support while we divide the tissues directly on it.

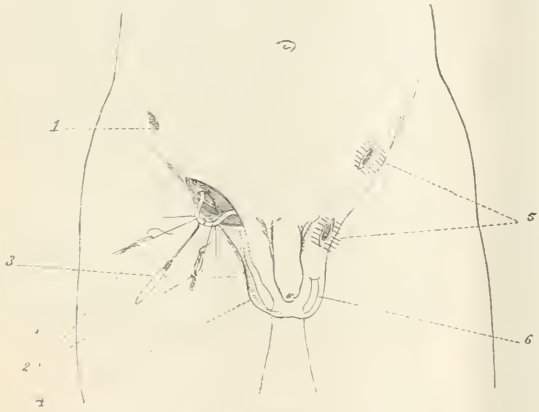

Fig. 2.—Showing the Raised Neck of the Sac through the Inguinal Incision. 1, Iliac incision; 2, free loops of ligature; 3, collapsed neck of sack; 4, atrophied testis and distended sac; 5, incision; 6, retracted divided sac.

This completes the first stage of the operation. We begin the second by withdrawing the index-finger and raising the sac on a tenaculum (Fig. 2), and making tension from above downward. Then, with a needle carrying a double-looped suture, the neck is transfixed, and its lumen closed by a firm square knot, when tension is made from above and it is cut through with the scissors. The distal end is now drawn immediately downward and lost from sight by its own contraction, while the proximal end rises by contraction up the inguinal canal. Now, with a long needle perforated near its point and fixed in a handle, we carry each loop up separately through the inguinal canal, the internal ring, and out through the iliac incision through the parietal peritoneum. Each of these loops should emerge through the fascia transversalis about three lines apart. In performing this part of the operation we may introduce the needle from above or below (Fig. 3).

After the loops are both well drawn out, through above, and the neck of the sac is wedged in and anchored between the parietal peritoneum and sheath of the transversalis muscle, they are firmly knotted and cut off. We are now ready for the third and last stage.

After all hemorrhage is subdued and the wounds are rendered thoroughly aseptic, we close in both incisions hermetically with continued catgut suture and apply the usual dressings.

Fig. 3.—Showing the Armed Needle from Above or Below. 1. Free loops of sutures sent up from below, or down from above; 2, needle handle; 3, emerging armed needles.

In femoral hernia in the male the lower incision is made external to the scroto-femoral fold; the upper, through the conjoined tendon extending down to the peritoneal reflexion, below the course of the internal epigastric artery.

As this species of hernia seldom attains a considerable volume, we will not be obliged to very often vary the position or direction of the incision (Fig. 4). Although no opportunity has yet presented itself to me to apply this method on the female, still it is my conviction that it will prove equally efficient with her.

We will not, in this type, be embarrassed by the presence of the spermatic cord, as in the male; and therefore it should be performed with greater ease and rapidity, without the probabilities of relapse (Fig. 6).

The case illustrated by Fig. 7 was a boy, seven years of age, who since he was three years old had a rupture. For a long time he could wear no description of a truss with comfort, and the protrusion was steadily increasing in size. Although the hernia came well down into the scrotum after reduction, on dissection it was found that the sac was drawn up so far into the inguinal canal that only its conical tip protruded through the external ring. This was

Fig. 4.—Showing Relative Position of Incisions for Inguinal Hernia—Right Side, Female. my care, having been operated on June 17th, and was photographed the day before. It is included here in order to illustrate, first, an incomplete, indirect, ingui-

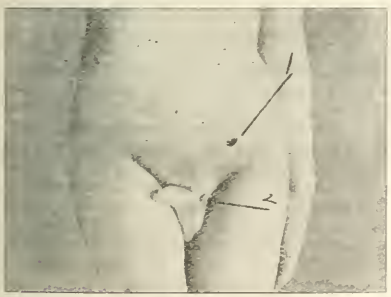

Fig. 7.

nal hernia, with some of the anatomical features of a cystocele of the cord; besides, to note the relative position and direction of the incisions in this type of hernial infirmity.

Fig. 9 is a photograph from a young man who came to me for treatment for rupture. The mass was not a hernia, but malignant disease of the testis, spermatic cord, and the retro-peritoneal tissues, compressing the cava, and thus producing a very varicose dilatation of all

Fig. 8.

the peripheral veinous channels. The disease speedily ended mortally, and was proven to be an adeno-sarcoma.

Conclusions.—From the rudimentary description of the Australian operation and the diagrammatic sketches here inserted, it is hoped that one may be better enabled to comprehend the principles on which it is founded. None, to my knowledge, so highly commends itself, for the many reasons here set forth.

With a procedure of so much promise, and one which has stood the repeated test of application on various types of inguinal hernia, without relapse in a single case yet, there should be a large field for its employ-

Fig. 9.

ment. With time, and perhaps some minor improvements in detail, there should be still better reports from it.

In order to realize the fullest advantages from it, however, caution and discrimination must be exercised in the selection of cases. In operation, rigorous asepsis is the foundation of success, for contamination of the tissues will lead to serious sequelæ that have no legitimate place in the formal operation.

Note.—The drawings in this article were made through the kindness of Dr. A. D. Davidow.

115 West Forty-ninth Street.

THREE CASES OF ABDOMINAL SECTION FOR EXTRA-UTERINE PREGNANCY, PRESENTING UNUSUAL FEATURES.

By EMORY LANPHEAR, M.D., PH.D.,

ST. LOUIS, MO.

FORMERLY PROFESSOR OF OPERATIVE AND CLINICAL SURGERY IN THE KANSAS CITY MEDICAL COLLEGE AND PROFESSOR OF THE PRINCIPLES AND PRACTICE OF SURGERY IN THE ST. LOUIS COLLEGE OF PHYSICIANS AND SURGEONS.

THREE of my operations for extra-uterine pregnancy have presented unusually interesting features: the first on account of the long time which elapsed between the date of rupture and that of operation, yet attended with satisfactory results; the second by reason of the peculiar difficulties encountered; the third because the diagnosis and operation were made prior to rupture of the tube.

Laparotomy for Extra-uterine Pregnancy on the Fifteenth Day after Tubal Rupture—Recovery.—On August 16, 1892, I saw Mrs. Belle W——, at her home, four miles south of Hamilton, Mo., in consultation with her physician, Dr. Tinsley Brown. She was forty-two years of age, the mother of two children aged eighteen and fourteen years. She was pregnant a third time in 1888, but miscarried at the fourth month, and never fully regained her health, menstruation being profuse and retroversion so marked and painful as to require frequent local treatment by glycerine tampons, etc. Her last menstruation was a little before June 1st, after which there were some of the usual symptoms of pregnancy. August 2d she was seized with an excruciating pain in the left ovarian region and a sharp hemorrhage occurred from the uterus. This bleeding soon ceased, but the pain continued in a modified degree. She became very weak, and by the time Dr. Brown reached her she was in profound collapse; pulse almost imperceptible; patient nearly unconscious, and the abdomen greatly distended: the usual signs of internal hemorrhage. But under stimulants she rallied, and at the time of my examination she was in fair condition, though the temperature was 101° F. The diagnosis of ruptured tubal pregnancy was positive.

At 9 A.M. next morning, with the assistance of Drs. Brown and Lindley, of Hamilton, I curetted the uterus, removing decidual membrane and decomposing blood-clots—evidently the cause of the elevation of temperature—and packed the uterus with gauze. Then I opened the abdomen and turned out a gallon and a half of fluid and clotted blood mixed with serum from the peritoneum, in which was found the fœtus. The torn ovary and tube were removed and the abdomen and pelvis thoroughly irrigated with boiled water until no more clots came away, as much of the fluid sponged out with aseptic gauze as could be removed without too much irritation of viscera, and the incision closed without drainage, with the usual dressings.

Convalescence was prompt and satisfactory in every respect. The afternoon temperature was 100° F. (the morning register just before operation being 102° F.), and sank a half degree daily until the normal was reached. The sutures were removed on the tenth day and she sat up on the fourteenth. In four weeks she began to do her own housework, and has since that time been in better health than for many years before the operation.

The remarkable features of this case are the rallying after such a serious hemorrhage, the long period that elapsed between the accident and the operation, and the speedy recovery under such circumstances.

I am not in favor of irrigation in most cases of abdominal section; in a case like this, where blood-clots were many and in almost every part of the abdomen, there was nothing else to be done; but the abdomen having been fairly well cleaned and dried, drainage could have but added to the danger.

Ruptured Tubal Pregnancy Complicated by Œdematous Myoma—Laparotomy and Hysterectomy under Difficulties—Death.—May 1, 1892, I was called to see Sarah B——, colored, aged about thirty-eight, who had been married seven years, but never became pregnant, so she supposed. For several years she had suffered from a uterine tumor of large size, for which ergot had been taken with little benefit. She last menstruated in January, 1892, but besides the cessation of menses no signs of pregnancy were noticed, so the ergot was continued vigorously.

April 30th.—In the afternoon labor pains began, and became quite severe in the evening, at which time her physician, Dr. A. L. Hunt, examined her, finding no dilatation of the os and no discharge. Morphine was given. At 6.30 A.M. the patient experienced a sudden, sharp, cutting pain in the right inguinal region and became unconscious. At 8 o'clock she was seen by the doctor, who found her in profound collapse, almost pulseless, and with abdomen distended to farthest possible limits. He diagnosticated ruptured tubal pregnancy, but regarded the patient as dying; however, he gave powerful stimulants—brandy in as large quantities as possible, etc. At 4 P.M., much to his surprise, he found the woman still alive, and so suggested operation. The abdomen was now filled with blood, almost to the point of bursting, it seemed.

At 5 P.M., assisted by Drs. A. H. Cordier and J. C. Maxson, of Kansas City, Dr. Hunt administering the ether, I opened the abdomen. The operation was performed in a lonely negro cabin of two rooms, a hovel, upon a door from an outhouse resting upon two boxes, the instruments occupying the only table. One tin wash-basin, an earthen bowl and plate, a bucket, a boiler of hot water and a quart cup constituted the "facilities" of our operating-room. Fully three quarts of blood gushed from the peritoneal space. A four-months' fœtus and placenta were found under the liver floating in blood which came from a huge rupture in an enlarged tube. As the clots and liquid blood were cleaned out it became evident that active hemorrhage was still going on; so the tube with its extensive tear was brought into the wound and the ovarian artery found bleeding copiously. It was very much enlarged, probably because the whole pelvis and lower abdomen were filled by a large solid tumor of the uterus. The artery having been tied, we next attempted to remove the injured tube, but it was so intimately blended with the tumor, and the tear extended so deeply into the uterine tissue, that this was found impossible. We next tried to pull the tumor forward and stitch the ruptured portion into the lower angle of the abdominal incision; but the tumor was so friable that no such sutures would hold—no matter how deeply they were passed they would at once cut through, just as if the tumor were half decomposed—so this plan had also to be abandoned. There remained nothing to do except to remove the tumor. But here a new difficulty confronted us. No one had anticipated the necessity of a hysterectomy, so there were no instruments at hand save those always found in my emergency operating-case. Means had to be devised as we progressed. I was in favor of making total extirpation as probably speedier and safer with the means at our command; but Dr. Cordier objected, because, 1, the vagina was unprepared, and therefore frightfully foul; 2, the large size of the tumor would greatly prolong the operation, and no rubber constrictor was at hand to control hemorrhage if we cut the tumor away; and, 3, under the circumstances there would be less loss of blood by making a pedicle than by removal of the entire uterus. We therefore pulled the tumor and uterus strongly into the opening, ligated and severed the broad ligament, and began the process of stripping downward to form a pedicle, Dr. Cordier working in front while I attacked the posterior surface. We thus quickly formed a satisfactory pedicle and introduced our "hysterectomy pins," these con-

sisting of the blades of long dressing-forceps thrust through the tissues at right angles to each other. An exceedingly strong silk cord which I happened to possess was thrown around the pedicle below the "pins," and with all our strength we pulled and pulled, and then tied; once more around and another pulling and tying, and we cut away the tumor. Our improvised constrictor acted as well as the most perfect serre-nœud and wire, not a bit of bleeding following; but to be sure of hæmostasis we pulled the two flaps of peritoneum which had been stripped from the tumor upward over the stump and stitched it over and over with catgut, then fastened the stump in the incision in the usual manner, irrigated the belly thoroughly, closed the cut, and applied our dressings. Remarkable as it may seem, the work was completed in forty-five minutes. No blood was lost after the ovarian artery was caught, but the previous hemorrhage was so great that in spite of the most vigorous stimulation she never rallied, death occurring within an hour after the completion of our work.

I have always censured myself that I tried to operate under such conditions. Knowing there was a large uterine tumor present, it would have been better, I am sure, to have used intravenous injections of normal salt solution, and ordered brandy, digitalis, liquid food, etc., waiting a few hours until the patient rallied from the shock and until careful preparation could have been made for hysterectomy with proper instruments. It is doubtful if the patient could have bled much more, as the abdominal walls seemed to have reached their limits. Yet at the time of operation I felt that the patient's only chance was in immediate section—an opinion with which Dr. Cordier coincided. So far as the operative work itself is concerned, I do not believe we could have done it any more quickly or more safely if we had had every instrument and appliance ordinarily at hand for abdominal hysterectomy.

Under more favorable surroundings this patient would, I think, have been better off by total extirpation of the enlarged and useless uterus.

The fœtus bore evidences of being at the fifteenth week of gestation. The membranes were not ruptured.

Tubal Pregnancy—Diagnosis before Rupture—Abdominal Section—Cure.—Mrs. Dora G——, twenty-four years of age, was brought to me March 20, 1894, by her attending physician, Dr. C. Lengel, of Kansas City, Mo. She was married at sixteen, and had a miscarriage at third month at seventeen; no trouble followed. At twenty-two she had prolapsus uteri, cause unknown, which Dr. Lengel cured by local measures, non-operative. Some tubal trouble began in May, 1893—pain, tenderness, and other evidences of salpingitis, with endometritis. These were relieved by glycerine tampons, application of iodine to the cavity of the uterus and vault of the vagina, etc. Menstruation was not interrupted, but continued regularly every twenty-eight days until six weeks before my examination, at which time the usual flow did not appear, nor did it come in another twenty-eight days. Having thus missed two of her periods, and feeling the usual signs of pregnancy—nausea, tenderness of the breasts, etc., she naturally came to the conclusion that she was enciente; but she became very anxious about herself on account of a peculiar sickening pain in the left side and a faintness from time to time. She therefore consulted her physician, who did not share her anxiety until March 18th, when a uterine hemorrhage occurred, not exactly like a menstrual discharge. He suspected tubal pregnancy and so called me into the case.

Examination showed the uterus pushed a little to the right, and (I thought) some enlargement of the left tube; a bloody discharge from the uterus; upon slightly dilating the cervix a small curette was easily introduced and brought away shreds of tissue resembling the decidua vera. There being such evidences of ectopic pregnancy I had the patient placed in St. Joseph's Hospital, where I operated with the assistance of Drs. T. B. Thrush and J. C. Maxson. The left tube was found the seat of pregnancy, neither sac nor tube having yet ruptured; it was readily removed without drainage, and convalescence was rapid.

Now why did I make the diagnosis of tubal pregnancy and operate? Especially why did I have the courage to operate in the face of Lawson Tait's opinion that diagnosis before rupture is almost impossible? In his "Lectures on Ectopic Pregnancy," page 49, Mr. Tait says: "The strangest thing to me is that, in the enormous experience I have now had in tubal pregnancy,[1] I have never but once been called upon to make an examination until the rupture occurred, and in that case there was neither history nor symptoms which enabled me to do more than to determine that there was tubal occlusion. Under these circumstances I think I may be excused for maintaining a somewhat sceptical attitude concerning the correctness of the diagnosis of those gentlemen who speak so confidently of making a certain diagnosis of tubal pregnancy before the period of rupture. The great bulk of the utterances in these directions may stand very well in 'society discussions,' but they will not stand the test of 'bedside experience.'"

But it must be remembered that this was written in 1889, and at a time when the advocates of puncture of the tube and destruction of the fœtus by electrolysis were enthusiastic in pushing their theories, and were antagonizing Mr. Tait's plan of treatment by cœliotomy.

In five years there were great advances in our knowledge of the subject. There was an almost universal adoption of the proposition that the safety of the mother lies only in early operation; and intelligent practitioners everywhere were on the alert for such cases, studying carefully every case of pregnancy in which there was the slightest irregularity. As a consequence of this increased interest and closer study I knew of a number of instances in which a diagnosis had been made prior to rupture[2] and the correctness of the opinion demonstrated at the operation. This was the first point that influenced me in favor of abdominal section.

The second point in favor of operation was that the history and symptoms pointed almost unmistakably to tubal pregnancy, viz., the woman had been once pregnant; there was then a long period of sterility, with the history of a salpingitis—a very important item because Tait says that "ectopic gestation is always caused by destruction of the proper epithelium of the tube by inflammation" (Lectures, p. 5). There was the cessation of menstruation and symptoms of pregnancy; the tube on one side was enlarged; there was no fœtus in the uterus, which was bleeding, but there were evidences of the presence of the decidua vera—not certain, but reasonably sure; and there was the existence of the peculiar pain described by Joseph Price as "a severe, paroxysmal pain—a sickening, pelvic pain which is neither cramp-like nor colicky, though often described by these terms."[3]

The third point was, there was unquestionably some trouble with the left tube, which probably demanded removal; and even if not, there was practically no danger in an exploratory operation if the rules of perfect asepsis were scrupulously followed.

A noteworthy feature of this case is the fact that the tenth week of gestation was passed without the least sign of probable early rupture of the tube or of the fœtal membranes.

2312 Salisbury Street.

[1] His experience at that time consisted of thirty-nine operations with two deaths.—E. L.

[2] Quite a number of these cases have been reported in Kansas City and St. Louis by men like Crowell, Cordier, and Summa.

[3] Extra-uterine Pregnancy, p. 16.

PAROVARIAN CYST, COMPLICATED BY THE PASSAGE OF RENAL CALCULI, SIMULATING AND DIAGNOSED AS ECTOPIC GESTATION—OPERATION.

By KARL W. DOEGE, M.D.,

MARSHFIELD, WIS.

Any pathological condition simulating a trouble of as serious a nature as ectopic gestation should command our attention immediately. It is for this reason that I wish to report the following case :

Mrs. A. H——, aged twenty-eight, is a hard-working farmer woman ; mother of two children, the oldest being five years of age, and the youngest one. Has menstruated three times since her last confinement, and always regularly, the flow lasting from five to six days. Her last menstrual period, which occurred about one week previous to the commencement of her trouble, did not last as long, nor was the flow as profuse as on former occasions. While feeling in perfect health, and after having assisted at harvesting during the day, she was suddenly seized with severe pain during the night, wakening her from her sleep. The pain was extremely violent, situated in the right side and accompanied by profound shock. Seeing her about six hours from the commencement of her trouble, I found her covered with clammy perspiration. Hands and feet were cold. She was shivering. Expression of face pinched. Pulse 92, but not especially weak, and temperature below normal. On palpation there was great sensitiveness in the right inguinal and hypogastric region. The vaginal examination was not satisfactory. On account of the extreme tenderness, only an expression of abnormal fulness could be obtained. The vault of the vagina to the left of the cervix contained a number of enlarged and forcibly pulsating arteries, running in a lateral direction. Patient thinks herself pregnant, in spite of having menstruated but a week ago. No urinary symptoms are present. Without making an attempt at an exact diagnosis, the rupture of a blood-vessel in the pelvis was thought probable, and treatment applied accordingly. On account of patient's belief of pregnancy, and considering the previous slight menstrual variation, the enlarged and tortuous arteries in the vault of the vagina, and fulness of the latter, the diagnosis of ectopic gestation was held in reserve, to be verified or disproved, if possible, at a future examination.

The passage of a renal calculus was thought of, but rejected, there being no urinary symptoms of any kind. Instructions, however, were given to watch the urine for the next two or three days. Under rest, cold, and morphine, the pain and sensitiveness gradually subsided after three days, the patient feeling perfectly well. No calculi were discovered. She failed to appear for subsequent examination.

Next month she menstruated in due time, but again not as usual. This time the flow was prolonged, not as free, and interrupted repeatedly. No membrane was passed and no discomfort felt while flowing. The day following the ceasing of the flux she again was seized by an attack exactly like the one four weeks ago. The shock this time was probably not as severe as before. Under similar treatment this also passed off in four days, but recovery did not appear to be as complete as heretofore, slight jars while walking causing uneasiness in lower part of abdomen.

A week later she presented herself for examination. On palpation a fulness and sensitiveness of the right inguinal and hypogastric region could be made out. On bimanual examination a tense, clearly cystic tumor was felt, located almost centrally. It seemed to be the size of an orange, slightly movable, lying close to the left of the uterus, very sensitive to pressure, and was coursed by large tortuous arteries at its lower presentation. The uterus was slightly enlarged and its fundus pushed well into the right inguinal region.

Considering the paroxysmal and tearing nature of the pain, the presence of a tumor, the tortuous blood-vessels, the enlarged uterus, and the slight menstrual disturbances, ectopic gestation was thought highly probable and an operation urged.

A week later she came to St. Joseph's Hospital, and assisted by Drs. Lathrop and Budge I opened the abdomen, and a cyst about the size of an orange was found. It was coursed by numerous blood-vessels. Its walls were thin and transparent, showing dark and bloody contents. It proved to be a parovarian cyst. While trying to shell it out from its serous covering it broke. A smart hemorrhage followed, which was readily controlled by clamping its base. Three or four smaller cysts were seen and removed with it. The left and right tubes were healthy. The cyst wall after excision showed a dark bloody spot, about the size of a twenty-five cent piece, where undoubtedly a rupture of a blood-vessel had taken place, thus accounting for the bloody contents.

The findings certainly disproved our diagnosis of ectopic gestation. On the other hand, they did not offer a quite satisfactory explanation as to the exact cause of her two previous attacks. Even with the undoubted fact that hemorrhage had taken place into the cyst, and assuming the woman to be of a highly sensitive disposition, it was not probable that so severe a pain and signs of collapse should be caused by a slight intra-cystic hemorrhage.

The woman made an uninterrupted recovery. She was to leave the hospital on the twenty-first day. The evening before her expected departure she expressed to one of the nurses a desire to stay in the hospital a little longer, her home environments not being quite as cheerful as could be. Two hours later she began to complain of severe and darting pains, similar to those of her previous attacks, only situated a little higher, just below the ribs. There was again the same collapse and the same cold perspiration, though not as severe as formerly. Morphine quieted her, and she was better the next morning. No urinary symptoms, except a moderate frequency of micturition on the day previous to the attack, had been observed. The immediate result, however, was that she stayed in the hospital a little longer. Since that day, however, I regarded her very sceptically, believing her hysterical and simulating the attacks. After one week she left the hospital, and expressed herself as feeling well, with neither pain nor tenderness.

About three weeks later her husband entered my office one morning and presented me, at the request of his wife, with something that she evacuated from her bladder about a week previous. It had been passed with considerable pain and much straining. I beheld a typical vesicular calculus, not quite round, a little larger than a lemon-seed. It was white in color, and from its surface were seen protruding three smaller calculi, evidently renal in origin, about the size of a hemp-seed each, and yellowish brown in appearance. This little stone to me told quite a story. Whatever had been doubtful and mysterious about the case was certainly now as clear as day. We had a case of parovarian cyst complicated by the passage of renal calculi.

As regards the tardy appearance of these calculi we have two possibilities : 1. The calculi of the first two attacks may have been passed unnoticed. Those of the third attack, *i.e.*, after the operation, there being several in number, were retained in the bladder, because the woman always occupied a recumbent posture and used a bedpan for urinating. Under these circumstances the calculi would not be very apt to pass, gravitating as they would to the posterior part of the bladder. Here they came in contact with each other, and were finally encrusted, thus forming a single vesicular calculus, which, after the woman had left her

bed, began to cause trouble and was eventually passed. 2. We may assume the existence of a slight ectasic condition of the bladder. The calculus of each of the three attacks (there being three renal calculi in the specimen) were retained in a little pocket, were encrusted, and finally evacuated as a single object.

We might well ask ourselves how could we have avoided our error before and how after the operation? Before the operation, there being a complete absence of all urinary symptoms, the probability certainly pointed very strongly toward ectopic gestation. After the operation the discrepancy between the small cystic hemorrhage, which in reality caused little or no pain, and the previous stormy paroxysmal attacks, should have put us on our guard, thus preventing the diagnosis of hysteria.

To be just to myself I may state that at the last attack I again did think of calculus, yet dropped that possibility for the more convenient hysteria, the latter certainly offering the easiest way out of the dilemma.

I have reported the above case because in my opinion these coincidences should be thought of in all such cases of supposed ectopic gestation where the symptoms do not make an exact diagnosis possible. Besides their practical value, theoretically, such discriminations are highly satisfactory and pleasing.

RHEUMATISM AS A CAUSE OF APPENDICITIS: POINTS IN ITS MEDICAL TREATMENT.

By BEVERLEY ROBINSON, M.D.,

NEW YORK.

The etiology of appendicitis in many instances is still very obscure, both for physicians and surgeons. It is therefore satisfactory to become convinced, by careful clinical observation, that one has found an obvious and frequent cause of numerous cases of a disease which is frequently fatal.

To my mind this cause is rheumatism. The judgment I now hold definitely about this matter is not an opinion reached rapidly and without carefully weighing the observations and reports of others. After several years of close inquiry into the origin of those cases I have met with or read about, I have not been able to explain apparently inconsequent facts from any other stand-point. I do not remember personally to have seen an attack of acute articular rheumatism either directly precede or follow evident signs of appendicitis, and to be connected with it in such a way that the relation of the two affections was clearly defined. Although this statement is correct of my own experience, it is not true of others. And already more than one such report has been made. When it comes to the milder, and, according to some, perhaps less characteristic symptoms of rheumatism, these I have repeatedly observed in patients who have had one or more attacks of appendicitis. Again, I have seen more than one patient who, subsequent to attacks of appendicitis, have had decided articular manifestations, and, during many years of this rheumatic localization, the appendical region has remained entirely free from any inflammatory disease.

There is really nothing rational to urge against rheumatism as a frequent cause of appendicitis. That rheumatic inflammation should attack this region very often is only what we should expect, if we consider the close relationship of the appendix with the peritoneum: and the fact that this serous membrane, like the pleura or the pericardium, is precisely the structure for which rheumatism, when it leaves the joints, has a special predilection.

The sudden development of many examples of acute appendicitis does not in any degree militate against rheumatism as an efficient and frequent cause of it, since the sudden and rapid development of acute rheumatic inflammation is true of the tonsils, the ovaries, the uterine appendages, and the joints themselves. The rapid progress toward suppuration is no reason to rule aside my explanation, since acute quinsy with suppuration, now well known to be of rheumatic origin—as salpingitis with speedy formation of an abscess cavity of like origin—is no uncommon finding.

No doubt in many cases which I might easily report, exception could be taken by the reader to my diagnosis of the rheumatic cause of appendicitis, in view of possible error of interpretation. Here, again, as in most things medical—particularly where clinical manifestations are seemingly doubtful until repeated experience has corroborated proof—we are forced to apply the touchstone of wise therapeutic interference. In this connection I cannot but affirm that treatment with salicin, or the salicylates, in sufficient and frequently repeated doses, has, in my experience, diminished pain and inflammatory manifestations in the appendical region more frequently than any other routine method of treatment. In many cases, I am now thoroughly convinced, suppuration has by this means been mainly avoided. Not that other remedial measures of a suitable kind should not be instituted. Among these I place as very important liquid, or low diet, and relative rest. In very acute cases, of course, with pronounced fever and vomiting, entire rest in bed, and liquid diet solely, are imperatively required. In these instances, moreover, I would insist in the beginning upon the local application of poultices, or the ice-coil, or ice-bag. I usually prefer repeated poultices, as I believe them more suitable to resolution of rheumatic inflammation. Again, I should rely upon moderately large laxative enemata to free up constipated bowels in those persons who have very marked general reaction. In numerous instances, I am equally satisfied, where the general reaction is not so pronounced, a mercurial in the form of six or eight grains of gray powder, or an equal dose of blue mass, serves a better purpose. I do not believe it increases the danger to the patient, as I do not believe it increases the peristaltic action of the bowels to any appreciable extent, and I am of the opinion that it promotes the flow of bile, which, in more ways than one, is directly useful. Of course, in some cases where pain is very severe, anodynes should be resorted to, and in extreme instances of this kind hypodermic injections of morphine are our final resort. Yet let us bear in mind that like the operation itself, unless obviously called for, it is bad treatment—radically bad—if my belief in regard to the causation of many cases of appendicitis be correct and sustained.

I cannot but think, even as I write, of an opinion held by one of our most eminent surgeons, viz., that in prescribing a drug the same care and knowledge should be exercised as in performing a severe surgical operation. Evidently the thought passing through the mind of this great exponent of his side of the question, was the distinct conviction of the untold harm accomplished by ignorant interference, seemingly trivial in character. Now, morphine, of all drugs, is the one that locks up most rapidly and completely our secretory functions. It is true of the kidneys, the stomach, the bowels, the liver, the respiratory organs, in one way or another. How, then, can it be rational, when we wish, above all things, to promote and further rapid secretion and excretion, to employ, in very active manner and doses, the drug that arrests it all? Pain is present, is the answer, and pain must be subdued. Yes, I reply, but make the attempt first of all, and as long as you should, with drugs that will not be manifestly harmful. Codeine, in frequent and sufficient doses, will often advantageously take the place of morphine. It does not lock up secretions to anything like the same de-

gree; it does not nauseate or constipate much, as a rule. It does mitigate, and sometimes abolish, pain. It allows time to be utilized so as to use the proper remedial drug—viz., salicylate of soda—and thus it guards the patient not infrequently against surgical interference, which is the ruling spirit of the hour. I do not wish to be considered as one of those who object at all to laparotomy in appendical inflammation, when surgical interference is called for. I do wish at this time to point out the medical way in which much that is beneficial may result, and considerable harm may be avoided.

In conclusion, I would add that local depletion with leeches, or wet cups, over the painful region, in patients of full habit, remains at present, as during the past, a proper and judicious abortive treatment of appendicitis.

THE ACTION OF THE DIPHTHERIA ANTITOXIN UPON THE KIDNEYS.

By WILLIAM VISSMAN, M.D.,

NEW YORK CITY.

LECTURER ON PATHOLOGY AND CLINICAL MICROSCOPY IN THE NEW YORK POLYCLINIC.

As is well known, the mortality from diphtheria is exceedingly variable, ranging from about twenty to seventy per cent., according to locality and the character of the epidemic. From time to time new remedies have been asserted to be specifics, only to lose their "specific" qualities with the next succeeding epidemic.

We were rather certain as to the etiology of the disease in question, until some of the opponents of diphtheria antitoxin began to question the causative relation of the Loeffler bacillus. At all events the opponents have shown, and some of the most ardent bacteriologists (Loeffler, Fraenkel, and others) agree, that the Loeffler bacillus is not found in every case of diphtheria; furthermore, that it is found in the throats of healthy individuals. Again, we must admit that, when lower animals are inoculated with this organism, they do not manifest the same anatomical lesions found in persons suffering with true diphtheria. It is true, if we remove the epithelium from the mucous membrane of the vagina of a guinea-pig, and then infect the denuded surface with the Loeffler bacillus, a pseudo-membrane is formed: but it differs from the pseudo-membrane formed in true diphtheria of man in that it remains confined to the seat of inoculation, while in man it spreads rapidly. However, it is not our aim to fully discuss the etiology of diphtheria in this place.

From the voluminous literature upon the treatment of diphtheria with antitoxin, we find that the views of the effect of the serum treatment are vastly different. The statistics of some clinicians show excellent results with this treatment, while others show little or no better results than those obtained without its use. Still others report most excellent results from the employment of other methods. Some of these results are as follows: Baginsky used antitoxin in 303 cases, with 40 deaths; and in 230 cases treated with other remedies there were 110 deaths. Carson treated 44 cases with antitoxin, and 75 per cent. recovered; of 66 cases treated with other remedies, 70 per cent. recovered. Sonnenburg employed serum in 95 cases, with 79.4 per cent. recoveries; and in 116 cases treated by other methods there were 72.4 per cent. recoveries. Guttmann treated 81 cases with pilocarpin, and all recovered. Aufrecht used chlorate of potassium, internally and as a mouth wash, in 264 cases, with but 1 death. With good nourishment and cleansing the mouth, Kust treated 144 cases, with a mortality of 12.

From the vast difference in the virulence of various epidemics, it is plain that the statistics now at hand are not sufficient to warrant any definite conclusion as to the merits of antitoxin in the treatment of diphtheria. Hence we must consider the effects in individual cases. But here, too, we find competent observers reporting very different results. Some have seen the disease vanish as if by magic; others have seen their cases recover gradually; and others, again, have seen little or no effect, or an ill effect.

Nearly all are agreed that there are certain disagreeable results from its use in some cases. Among these complications are erythema, hemorrhages in the skin, heart weakness, pain in the joints with or without swelling, which may last for several days. A few have observed albuminuria more frequently, others less frequently, while still others consider albuminuria an indication for the administration of more antitoxin. Since albuminuria is rather a frequent complication of diphtheria, it is rather difficult to determine whether it is the result of diphtheria or the antitoxin.

To obtain light upon the effect of antitoxin on the kidneys, diphtheria antitoxin, kindly furnished by Dr. Paul Gibier, of this city, was injected into healthy rabbits. Upon the suggestion of Dr. Gibier an effort was made to collect the urine from the animals for examination previous to the experiments. This, however, was not accomplished. Consequently, every animal was accompanied by a control animal. The animals were divided into two series, the first series into two groups of six animals each. The animals used (rabbits) weighed between three and four and a half pounds. In the first group of the first series each animal received an injection of 1 c.c. of antitoxin. In the second group, each animal received 2 c.c. In the second series (three animals) each received 1 c.c. on three consecutive days. In both groups of the first series an animal was killed each day, until the groups were exhausted. In the second series, after the third injection one animal was killed every day until the group was destroyed. As the character of the lesions was the same in all of the animals, varying in intensity with the size of the dose administered, it will not be necessary to give a detailed account of the changes observed in each animal. At the site of injection there was a nodule which extended over a radius of about an inch from the point where the needle had entered. The nodule was slightly painful on pressure, but the general condition of the animals was good so far as could be observed. At the end of the second day the lump began to grow smaller, and was scarcely perceptible on the animals killed on the seventh day after the injection.

On cutting through the nodule the subcutaneous tissue was found to be impregnated with a straw-colored, serous fluid, containing very few leucocytes. Part of this fluid was used for inoculating glycerine agar and gelatine, but at the end of three days no growth had appeared. As time elapsed, the œdema grew less marked, but the fluid was always found to be sterile.

As the object of the investigations was to determine the action of antitoxin upon the kidneys, little attention was paid to other organs, more than to note that the spleen and liver were slightly swollen and redder than normal.

The kidneys of the animals killed twenty-four hours after the injections were very firm, and of a dark-red color. On the cut surface the cortical substance was very much injected, slightly opaque, and a little more prominent than the medullary substance, which was pale in color.

On microscopic examination of fresh sections in 0.6 per cent. salt solution, the Malpighian bodies and capillaries of the cortex were found to be distended with blood. The epithelial cells of the tubules were filled with refractive granules obscuring the nuclei, which were only brought to view by the addition of dilute acetic acid. There were no casts found in the tubules. These conditions were found in all of the

animals, and, as the time after the administration of the antitoxin increased, the injection of the blood-vessels decreased and the cloudy swelling became more prominent.

In the animals of the second series, the only difference discernible was that the injection of the capillaries was more pronounced, and that there were a few slight hemorrhages into the tubules. Fatty metamorphosis of the epithelium was not observed in a single instance. It is highly probable that, had these sections been subjected to fixing by alcohol, or other fixing agents, the cloudy swelling above described would have been overlooked.

Since the doses administered to the rabbits were about equal, or a trifle less, proportionately, than the doses administered to children in cases of diphtheria, it is reasonable to suppose that, approximately, the same changes are brought about in children when antitoxin is administered. Certainly, this is assuming that a pound of rabbit is equivalent to a pound of human subject! Yet, this is no greater assumption than the first use of the remedy was based upon.

Strangely enough, the facts first adduced by Behring, and repeated by Roux, Parks, Biggs, and others, have received very little consideration. These observers, after ascertaining exactly how much antitoxin was required to neutralize a certain amount of toxin, found that if a definite dose of toxin was introduced with a definite dose of antitoxin, the animals suffered very little. If antitoxin was introduced about twelve hours before the toxin, the animals recovered. But if the order was reversed, *i.e.*, the toxin given twelve hours before the antitoxin, recovery was not the rule. The animals generally succumbed to the effects of the toxin. These experiments, carried out by the above-named authors, indicate that antitoxin has a certain antidotal effect when administered with, or very shortly before, the toxin; but after the toxin has once begun to affect the organism, the antitoxin has but slight, if any, power of neutralizing its ill effects. On the contrary, the experiments forming the subject of this paper would indicate that the antitoxin has a harmful influence, in that it impairs the health of the organism and would, consequently, reduce the power to resist the inroads of the disease.

As for the immunizing power, experience thus far has produced very little encouragement. To begin with, any number of persons have had diphtheria with all of its concomitant dangers, and this, too, in as short a time as twenty-four hours after the administration of supposed immunizing dose of antitoxin. Again, all admit that its immunizing powers are of but a transitory nature; indeed, it is of so short duration that, in almost all cases, it ceases long before the diphtheria bacilli disappear from the fauces or lose their virulence. From this it would seem that, if antitoxin is injected a very short while before the patient begins to manifest diphtheria, *i.e.*, before the pseudo-membrane is formed and before the real effect of the toxin becomes apparent, the patient may possibly be benefited; but since a large number of individuals have Loeffler bacilli in their fauces without suffering any embarrassment at any time, it is impossible to determine which of these persons should or should not receive the serum.

Since the injection of serum into rabbits produces a cloudy swelling of the kidneys, or an acute nephritis, as shown above, if all of these persons having virulent diphtheria bacilli in their fauces were treated with antitoxin, many would be injured for an uncertain benefit to a very few. After the disease has made such progress that it can be diagnosed, the toxin has produced such an effect upon the organism that, judging from the experiments of Behring, Biggs, Parks, and others, little benefit is to be expected from antitoxin. And since observing the results of experiments just reported on rabbits, it is highly probable that, instead of reducing the mortality of diphtheria, antitoxin has really increased the death-rate.

244 West 139TH STREET.

A CASE OF PERFORATIVE APPENDICITIS WITH GENERAL PURULENT PERITONITIS—OPERATION—RECOVERY.[1]

By FRANK D. GRAY, M.D.,

ATTENDING SURGEON TO CHRIST HOSPITAL, JERSEY CITY, N. J.

THE time has probably passed when every instance of appendicitis is worthy of special record, but certain interesting and somewhat unusual features of the following case make it, I think, of value to those of the profession who are interested in the subject:

J. E. R——, aged twenty-nine, colored, Pulman porter, applied to me at my office on the evening of April 9, 1895, for relief of severe abdominal pain located just at the right of the umbilicus. He had suffered since early that morning, having felt perfectly well the day before. Being in Washington, D. C., he applied at a pharmacy and was given a dose of castor-oil, which had no effect except to produce emesis. He attended to his duties on the trip from Washington to New York that day, although in much pain and having several attacks of vomiting. There was no history of previous attacks of the kind.

Temperature per orem was normal and pulse 80. There was no tenderness on pressure in either iliac region—in fact, the patient claimed that pressure over the seat of greatest pain relieved instead of aggravating it. Constipation had existed for several days and a hearty meal of rather indigestible food had been eaten the previous evening.

In view of this history I diagnosed intestinal colic, consequent on an acute attack of indigestion; administered one-fourth grain of morphine, hypodermically, and prescribed an active cathartic to be taken on retiring. I saw the patient next morning at his room and found him but little if any, relieved: the bowels had not moved—the pain still was persistent and of the same character as before, with absence of tenderness; temperature per orem still normal, and pulse about eighty. With the idea that free catharsis would give relief, I ordered drachm doses of magnesia sulphate, to be given hourly until the bowels moved, and hot fomentations applied to the abdomen.

At 8 o'clock that evening I received an urgent call to this case and on my arrival found the patient in a condition of partial collapse, bathed in cold perspiration, pulse rapid and thready, temperature 102.3° F. per rectum, and suffering excruciating pain, with exquisite tenderness over the whole abdomen and considerable tympanites. I at once realized that I now had to deal with a case of intestinal perforation from some cause, most likely perforative appendicitis, and that the only hope for my patient lay in an immediate cœliotomy.

The surroundings at his home being unfavorable for such an operation, I had him transferred at once to Christ Hospital, where he arrived at 10.30 P.M. and at 11 P.M. I operated, having associated with me Dr. G. K. Dickinson, of the surgical staff, Dr. J. M. Rector, and the house staff.

Owing to the uncertainty as to the exact location of the lesion and the great probability of finding general infection of the peritoneum, I adopted a median incision (about three and one-half inches in length). On opening the peritoneal cavity I found the intestines deeply congested, dotted with numerous small patches of adherent lymph, and bathed in a quantity of seropurulent fluid. The mesenteric glands were already much engorged, in fact all the appearances of a severe

[1] Read before the Hudson County Medical Society June 4, 1895.

general purulent peritonitis were present. I found the appendix only moderately thickened, with but slight adhesions to the adjoining intestine and none to the abdominal wall. It was perforated and contained a concretion closely resembling a date-seed in general appearance. In spite of this very unpromising state of affairs we proceeded with as much care as if we had every reason to expect recovery, though I must confess that we all feared it to be a routine that would be of little use to our patient. The appendix was ligated and removed, its lumen disinfected with ninety per cent. carbolic acid and closed with Lembert sutures, the intestines were thoroughly washed with large quantities of warm sterilized water poured upon them, and the abdominal cavity carefully dried, down to the depths of the pelvis, by sterilized sponges. A large iodoform-gauze drain was introduced, without a tube, well down to the bottom of the pelvis and brought out at the lower angle of the incision. A large portion of the intestinal canal had escaped from the abdominal cavity during the operation and was protected by warm sterilized gauzes. Owing to distention of the bowels this was returned with considerable difficulty and the wound closed with silkworm sutures. The patient rallied well, having but little shock, and rested well through the night, with no vomiting. No nourishment was allowed until 5.30 P.M., when he took and retained a half ounce of peptonized milk every hour.

On the third and fourth days after operation there were occasional attacks of green vomiting accompanied by hiccough, which gave me some anxiety, but these symptoms were readily controlled by hourly doses of calomel, gr. ⅛, and oxalate of cerjium, gr. i. On the occurrence of vomiting an attempt was made to move the bowels by enema, but without success. On the fifth day, however, the bowels responded to hourly doses of magnes. sulph., one drachm, followed by an enema; after this, salts or an enema were administered every second day with good result. For the first few days there was considerable tympanites, which gradually subsided after the introduction of a rectal tube. For the first ten days the patient complained of rather severe pain and tenderness over the entire abdomen, which, however, was controlled by an occasional hypodermic of morphine—usually one dose (never more than two) of one-fourth grain in twenty-four hours.

For the first forty-eight hours the gauze drain brought away a free watery discharge, becoming very scanty by the fourth day, when the wick was removed and replaced by a shorter one. The sutures were all removed on the fourteenth day, patient allowed to sit up on the twentieth day, and discharged cured, May 6th, twenty-six days after operation.

Following is the record of pulse and temperature for first six days—all temperature rectal:

											° F.
1st day	pulse ranged	from	100	to	120;	temperature,	99	to	100.8
2d	"	"	"	"	68	"	98;	"	99.4	"	100.2
3d	"	"	"	"	72	"	88;	"	100	"	101
4th	"	"	"	"	72	"	80;	"	99.6	"	101.4
5th	"	"	"	"	72	"	80;	"	100	"	100.2
6th	"	"	"	"	72	"	80;	"	97.8	"	99.8

After the sixth day, pulse and temperature remained normal.

The points of special interest which I would emphasize in this case are: First, the misleading character of the early symptoms, there being during the first twenty-four hours of the disease absence of fever, if we could believe the record of temperature taken under the tongue (I would remark here, by the way, that I think it is better practice to take the rectal temperature in cases of suspected appendicitis), also absence of that characteristic right iliac tenderness which we usually consider essential to a diagnosis of appendicitis. On the contrary, in this case the pain was apparently relieved somewhat by pressure.

Another point worthy of notice is the unusually rapid progress of the case. Within thirty-six hours after the inception of pain there was perforation of the appendix and general septic peritonitis.

Again note the rapidity with which purulent infection of the peritoneum took place after perforation. The patient says that a decided change in the character of his pain occurred about 7 P.M., it becoming greatly increased in intensity and accompanied by tenderness, cold perspiration, great prostration, etc. It is reasonable to suppose that perforation occurred at that time. Upon opening the peritoneal cavity four hours later we found a large quantity of sero-purulent fluid with beginning lymph exudates—in fact, all the conditions of the worst form of general peritonitis.

Lastly, and to my mind most important of all, is the fact that so desperate a case, to all appearances, should prove so amenable to prompt and thorough surgical measures. The history of this case after operation was no more serious than many an uncomplicated appendicitis; in reality, beyond a few attacks of vomiting and hiccough on the third and fourth days and a moderate degree of pain for the first week or ten days, there were no unfavorable symptoms.

So far as a single instance may go, it shows that we need not despair of the worst cases of this sort so long as we have the resources of prompt surgical interference, thorough cleansing of peritoneal surfaces, and free drainage.

Progress of Medical Science.

Cork Splints for Deflections of the Nasal Septum.—Dr. Berens reports excellent results from the use of a simple device for a splint in cases of fracture or operation for deflected septum nasi. Plugs of cotton or oakum become too readily foul, while the various supports which have been used have many disadvantages, the soft-rubber tubing being too yielding, while the hard rubber or ivory plugs cause too much pressure and pain. Berens makes his splints from corks in the following manner: A selected cork (pint-bottle size), in average length one and a quarter inches, in breadth at its broad end three-quarters of an inch, at its narrow end one-quarter of an inch less, is whittled to the shape of an almond with the point cut off, and flattened on the side that is to lie against the septum; the opposite side near its lower border is slightly grooved for the reception of the inferior turbinated body. A nasal burr or trephine is now used to hollow the splint, leaving the shell one and a sixteenth to one-eighth of an inch thick. A rat-tail file, a small-bladed knife or red-hot metal may also be used for this purpose. Sandpaper is used to smooth both the inner and outer surfaces, and the whole splint is then coated with flexible collodion, to which has been added iodoform in the proportion of thirty grains to the fluid ounce, allowed to dry and it is ready for use. The making of the splints requires no especial mechanical skill, and they can be modified with ease to suit the peculiarities of each case. The special advantages of these splints, which are possessed by no other similar device, are the quickness and ease with which they can be made and shaped to fit the peculiarities of each case; their cheapness, lightness, and elasticity combined with sufficient firmness to support the septum; their durability and non-conduction of heat and cold and non-interference with the free circulation of the blood; the ease with which they can be cleaned *in situ* by washing out with peroxide of hydrogen and boric-acid solutions, followed by an oily spray, as benzoinol, and the length of time they can be worn without pain, discomfort, or severe ulceration.—*Boston Medical and Surgical Journal.*

New York, September 14, 1895.

THE FUNDAMENTAL DIFFERENCE BETWEEN PLANTS AND ANIMALS.

As our knowledge of biology has progressed, the attempts to distinguish between animal and plant life have become more and more difficult. The commonly accepted distinction was based upon the difference between the synthetic or building-up process in the two biological series. The plant has the power of bringing free nitrogen into combination with other atoms, while the animal does not have this power. Dr. Minot, in an article published in *Science* of March 22d, says, that it is much to be regretted that this method of defining the difference between animals and plants has been so widely accepted, since it is not entirely true, and therefore leads to much perplexity. There are some plants without chlorophyll that cannot bring nitrogen into combination, and there are some animals in which synthetic processes occur. Another distinction often drawn, says Dr. Minot, between animals and plants, is that of the presence in the former of internal digestive organs, but this distinction also does not hold entirely true, for the amœba has no internal digestive organs at all, though it is classed as an animal. Dr. Minot thinks that we can best define the two primary divisions of the living world thus: Animals are organisms which take part of their food in the form of concrete particles which are lodged in the cell protoplasm by the activity of the protoplasm itself. Plants are organisms which obtain all their food in either the liquid or gaseous form by osmosis or diffusion. The writer admits that there are a few examples which somewhat militate against the acceptation of this distinction. The only class which he distinctly cites as an exception, however, is the myxocytes, and these, he suggests, form a link between animal and plant life. The tape worm, he admits, might be considered an example of an animal that lives by osmosis, but this animal may perhaps also take part of its food by the absorption of the concrete particles.

An animal, then, according to Dr. Minot, is an organism which takes its food in a solid form; a plant, one which takes it in a liquid or gaseous form. The animal lives through the vital activity of its protoplasm, stretching out its substance and enveloping the particles of food. Only in this way, by getting the concrete substance into its meshes, is the animal able to live. The plant, however, lives by osmosis or diffusion alone. Of course the animal also absorbs liquids and gases by this same process, and therefore includes in its vital functions some of those which are peculiar to the plant.

Dr. Minot elaborates his view of the essential characteristic of the animal in an ingenious way, showing that, owing to the fact that animal life depends upon the activity of its protoplasm, the animal is therefore compelled to exert itself. Its protoplasm is obliged to be kept in a state of activity, and hence the gradual development of the cells of the body into organs which help the animal in its pursuit of food and in the propagation of its species. In other words, it is harder to live on solid food than on a gaseous diet, since the former requires an active and positive effort on the part of the organism.

RAILWAY HOSPITALS FOR THE EAST.

THE International Medico-Legal Congress which met recently in this city was not productive of very great results, yet there were some rather interesting papers read.

Dr. George Chaffee, of Brooklyn, presented a communication entitled "Is the Railway Hospital System an Economy?" and he made a very strong and interesting plea in behalf of the extension of the railway hospital system to the lines in the East. Dr. Chaffee states that the hospital system, which is already so popular in the South and West, is now being seriously considered by the officials of some of the leading Eastern roads. He himself has been directing his efforts toward securing the adoption of this system in the East. Dr. Chaffee asserts that the hospital system is economical, practical, and self-supporting, and he presents some facts and figures to bear out this view.

It is objected that, in the East, such a system is hardly necessary, since all our large and even small towns are now well equipped with good hospitals; but to this he replies that the system by which railroads own and control hospitals is one which secures the immediate services of specially trained surgeons for the benefit of those injured in the employ of the railroads. The employees practically own and control the hospitals, and support them by small assessments which are paid pro rata by every individual in the employ of the company. The system, he believes, tends to lessen the amount of litigation connected with railroads, and also prevents many of the disastrous effects of railroad injuries. Particularizing the system still more, Dr. Chaffee makes these three statements:

1. "It does not cost the corporation one cent; the system is established and maintained by light monthly assessments upon the employees—from the President down.

2. "It favors compromise and prevents much litigation, a saving of thousand of dollars annually.

3. "Not only employees, but injured patrons as well, are cared for in the railway hospital without cost to the corporation, and are thus kept in the family circle instead of being placed—as is the case in many instances—directly in the hands of the enemy at their homes."

We have presented the claims made in behalf of the railway hospital system, and we find no record of any discussion in which such a system is opposed. It would be well, however, before the medical employees of the railroads of the East give their approval to such a system, to consider both sides of the question. Already we have great complaints about the evils of the contract doctor system, and Western journals contain a great deal of acrimonious discussion as to the rights of private practitioners and the encroachment upon them by the servants of the corporations. The establishment of the railway hospital system means an additional step in the syndicating of medical service. It means that a large number of medical men will become employees and practically clerks of great corporations. It means that such a class of men will lose, to a large extent, independence of spirit, and that the kind of work that they do will be classed more and more, not as professional services, but as a species of skilled workmanship, like that of a high-class mechanic. We do not say that all these disadvantages will outweigh the arguments that can be brought forward to sustain the other side, but we feel sure that the railway hospital system is one that is not quite so free from blemishes as the enthusiasm of Dr. Chaffee would make us think.

THE WEIGHT OF THE BRAIN IN THE SANE AND INSANE.

It would seem to be a rather easy thing to get at the facts regarding the weight of the human brain and its significance. This, however, has not proved to be the case, and even now, despite years of weighing and careful collecting of statistics, observers have hardly yet reached a certainty upon any of the facts connected with the volume of the human brain. Consequently a fresh contribution to this subject by Dr. A. Mercier is interesting and welcome. The title of his monograph is "The Diminution of the Weight of the Brain in General Paralysis." The author, however, gives more in his article than would be inferred from its title. He, in the first place, collects the statistics of brain-weights that have been furnished by other observers and says that, as a result of the study of the data thus collected, the weight of the brain of a normal European adult is 1,375 grammes for a man, and 1,245 grammes for a woman. He, however, adopts as the safer average the figures given by Weichselbaum and Pleger, viz., 1,353 for man and 1,200 for woman. The next point which Dr. Mercier takes up is the relative weight of the brain as a whole to that of the brain mantle. By this is meant the brain minus the cerebellum, pons, and brain-axis, these parts being carefully removed by a method specially described by the late Professor Meynart. It is found that, assuming the weight of the male brain to be 1,353 grammes, that of the mantle is 1,070. This is for the male brain. In the brain of an average woman weighing 1,200 grammes, the mantle would weigh 943 grammes. Using these figures as a basis, the author proceeds to compare the statistics of brain weights in the insane, and then gives the result of his own investigation as to the weight of brains of this class. Dr. Mercier's figures include 330 brains. Of these, 234 were from men, 96 were from women. The brains included in part cases of general paralysis, and in part cases of insane due to other causes, excluding, however, in all instances the brains of senile dements.

The author concludes that the brain-weight of man is greater than that of woman, and that in man the brain mantle is proportionately larger. In women, on the other hand, the cerebellum and brain-axis are proportionately larger than the rest of the brain. In general paralysis he finds that the weight of the brain is decidedly less on an average than the weight of a normal brain. This loss of weight affects especially the mantle. It furthermore affects especially the frontal lobes and, still further, it affects the left cerebral hemisphere more than the right. He finds also that in general paralysis there is a greater loss of brain-weight than in insanity due to other causes, leaving aside senile dementia. The average weight of the brain of the insane is not, in fact, very much less than that of the healthy man, leaving out of consideration the forms of insanity just referred to. The diminution of the weight of the brain in general paralysis shows its effect more strikingly in the brains of women than in those of men.

A LAYMAN'S IDEA OF EUTHANASIA.

Mr. Albert Bach, a lawyer and vice-president of the Medico-Legal Society, seems to have definite opinions as to the right of a man to take his own or another's life—opinions which, we trust, are not shared by the majority of his fellow-members of the Medico-Legal Society. At the recent congress, held in this city, there was quite a discussion upon suicide, in the course of which Mr. Bach ventured the assertion that a man has a right to kill himself under certain circumstances, just as a physician has the right to administer drugs to end the agony of a patient. He held that a physician has the moral right to end human life under these circumstances. Mr. Bach is, of course, at liberty to hold what views he will as to the taking of human life, so long as he does not attempt to carry them out in practice; but he unwisely goes further and says, not only that physicians may end life in order to cut short suffering, but that he knows they do.

That physicians give drugs to ease the agony of a dying person is true, for it is part of their mission to relieve pain and to rob death of its terrors, as far as they may, when they cannot avert it. But to argue from this that the physician kills his patient in order to relieve his sufferings, betrays a curious lack of reasoning power or a wilful abuse of it. To promote euthanasia is the right and the duty of the physician; to take the life of a dying man or to hasten his dissolution by the administration of drugs is no more justifiable in the physician than would be the ending of the patient's life by the stiletto or the pistol, or than poisoning is at the hands of some expectant heir or avowed enemy.

If Mr. Bach knows of any specific instances of the killing of patients he should give them, but he has no right to libel an entire profession and to misconstrue an act of mercy into what would be accounted a crime by all but those of his own way of thinking.

ST. LOUIS AND FREE DISPENSARIES.

St. Louis, having been greatly worried by the number of its medical colleges, and after having become greatly embittered through the strife between its medical societies, is having an interesting set-to between two of its journalists. Lest, even with all these things, life should still become stale and monotonous, the *Medical Review* has begun to lament the excessive number of its city dispensaries. The newly appointed health commissioner of the State, Dr. Starkloff, is, we are told, a very energetic gentleman, who is ambitious to have the city treat more people for nothing. He has consequently established four new city dispensaries. When these four new dispensaries are added to the eleven or thirteen medical colleges, and the private free clinics and free dispensaries connected with the hospitals, the sum total is alarming, and the *Medical Review* feels justly disposed to criticise the unnecessary zeal of the new health commissioner.

News of the Week.

The American Public Health Association.—The twenty-third annual meeting of this Association will be held at Denver, Col., on October 1, 2, 3, and 4, 1895. The headquarters for the meeting will be at the Brown Palace Hotel. The officers of the Association are: *President*, Dr. William Bailey, of Louisville, Ky.; *First Vice-President*, Dr. Granville P. Conn, of Concord, N. H.; *Second Vice-President*, Dr. Gregorio Mendizabal, of Orizaba, Vera Cruz, Mexico; *Secretary*, Dr. Irving A. Watson, of Concord, N. H.; *Treasurer*, Dr. Henry D. Holton, of Brattleboro, Vt. The following subjects have been proposed for discussion: 1, "The Pollution of Water-supplies;" 2, "The Disposal of Garbage and Refuse;" 3, "Animal Diseases and Animal Food;" 4, "The Nomenclature of Diseases and Forms of Statistics;" 5, "Protective Inoculations in Infectious Diseases;" 6, "National Health Legislation;" 7, "The Cause and Prevention of Diphtheria;" 8, "Causes and Prevention of Infant Mortality;" 9, "The Restriction and Prevention of Tuberculosis;" 10, "Car Sanitation;" 11, "The Prevention of the Spread of Yellow Fever;" 12, "Steamship and Steamboat Sanitation;" 13, "Transportation of the Dead;" 14, "The Disposal of the Dead;" 15, "The Abuse of Alcoholic Drinks from a Sanitary Standpoint." This Association is one composed of earnest workers in the cause of sanitation, who discuss much that might be of service to the community; but its usefulness is seriously impaired by a rule which forbids members to publish, in whole or in abstract, any paper read before the Association until after its publication in the official transactions. Very few people other than members of the Association see its volume of transactions, and the papers are therefore buried and practically useless.

An International Congress for the Study of Alcohol was recently held at Basle, Switzerland. Its membership was composed very largely of advocates of total abstinence, and all its conclusions were adverse to the use of alcoholic beverages. The next congress will be held in Brussels.

A Quarantine Brutality.—A man suffering from smallpox was recently expelled from Arkansas and refused admittance into Mississippi. As he could not well remain in or on the Mississippi River until the disease ran its course, he attempted to evade the quarantine and land on the river bank in the latter State, but was shot and killed by one of the quarantine officers.

A Pension of £200 a year has been granted to the widow of the late Professor Huxley.

The Morphine Habit in China.—According to an English contemporary the British consuls in China have repeatedly drawn attention to the increasing prevalence in several ports of the pernicious habit of injecting preparations of morphine, practised by unqualified persons among the natives. This custom was originally introduced as a cure for opium smoking, but it is a case in which the remedy is worse than the disease. Those who sell morphine and make the injections procure a profit of from two hundred to four hundred per cent. The charge for smoking an injection is one cent. One of the victims of the practice said: "It is much cheaper than opium smoking, and I get the same satisfaction out of it. I know of ten Chinese doctors, each of whom treats fifty to one hundred men daily with this medicine."

The Late Dr. Wollmann.—At a meeting of the Medical Board of the Beth Israel Hospital held August 28, 1895, the following resolutions were adopted:

Whereas, Our respected colleague and colladorator in the charitable work of the Beth Israel Hospital, Dr. Marcus Wollmann, has been removed from us by death;

Resolved, That we deeply feel and mourn the loss of an esteemed friend as well as member of our Board, whose career was so sadly cut short during the best period of his life; and that we tender to his sorrowing widow and family our sincere sympathy and condolence in their affliction. And be it further

Resolved, That a copy of these resolutions be spread on the minutes of this Board, and that a copy be sent to the bereaved family. Also that copies be sent to the medical press for publication.

A. E. Isaacs, M.D., *President.*
D. Robinson, M.D., *Secretary.*

Obituary Notes.—Dr. John Syer Bristowe died at Dixton Vicarage, Monmouth, England, on August 20th, aged sixty-eight. He had been out of health for some time, but the precise nature of his illness was not clearly understood. Dr. Bristowe was known in this country chiefly through his "Treatise on the Theory and Practice of Medicine," published in 1876. In 1888 he published a work on "Diseases of the Nervous System." He was also a frequent contributor of articles on various subjects to periodical literature. He delivered the Lumleian Lectures in 1879, on the "Pathological Relation of Voice and Speech;" the Lettsomian Lectures, on "Syphilis of the Nervous System;" and the Croonian Lectures, on "Disease and its Medical Treatment." Dr. Bristowe's father and grand-

father were physicians, and one of his sons is a practitioner and another a student of medicine.—Dr. Ernst Hoppe-Seyler, Professor of Physiological and Pathological Chemistry at the Kaiser Wilhelm University in Strassburg, died of apoplexy on August 10th, at his summer residence on the Bodensee. He was born in 1825 in Freiburg, in Thüringen. He began practice in Berlin in 1852, was then privat docent at Greifswald for two years, when he returned to Berlin. In 1861 he went to Tübingen and in 1872 to Strassburg, where he remained the rest of his life.—Dr. Joannes Ch. Bambas, editor of *Galenos*, died in Athens on August 1st. He was born in 1849, and after being graduated from the medical department of the National University at Athens, spent some time in study in Paris, Berlin, and Vienna. A few years after his return to Athens he was appointed Professor of Hygiene in the National University.—Dr. William S. Layman, of Schoharie, died at his home on September 5th, at the age of sixty-four years. He was a graduate of the Albany Medical College in the class of 1857.

The Lectures at the London College of Physicians for the coming year will be delivered as follows: The Bradshaw lecture by Dr. Bradbury; the Lumleian lectures by Sir Dyce Duckworth; the Gulstonian lecture by Dr. Mason; and the Croonian lecture by Dr. Oliver.

The Mississippi Valley Medical Association, at its recent meeting in Detroit, elected Dr. H. O. Walker, of that city, president for the ensuing year. The next meeting of the Association will be held in Minneapolis.

Wisconsin's Cholera Fund.—The Legislature of Wisconsin has appropriated $50,000 as a contingent fund to be used by the Health Board, if necessary at any time during the next two years, to prevent the introduction of cholera.

The American Social Science Association held its annual meeting at Saratoga during the first week in September. In the Health Department papers were read by the chairman, Dr. Frederick Peterson, of New York, on "The Craig Colony for Epileptics;" by Dr. L. Duncan Bulkley, of New York, on "A Plea for the Legal Control of Certain Dangerous Communicable Diseases;" and by Dr. Grace Peckham Murray, of New York, on "The Relation of Education to the Cerebral Development of the Child." Dr. T. W. Cheesman, of New York, delivered an address on "The Bacteria: What They Are; What They Do; How We Study Them." The lecture was illustrated with stereopticon views.

The following officers were elected for the ensuing year: *President*, F. J. Kingsbury, of Waterbury, Conn.; *First Vice-President*, H. L. Wayland, of Philadelphia; *General Secretary*, F. B. Sanborn, of Concord, Mass.; *Treasurer*, Anson Phelps Stokes, of New York.

The National Wholesale Druggists' Association will hold its next annual meeting in Philadelphia.

Cholera is reported to have broken out at Brusa, a town in Asiatic Turkey, about sixty miles from Constantinople, and a quarantine cordon has been drawn around the place to prevent the spread of the disease to the capital. The province of Podolia in Russia has been officially declared infected. The disease prevails also to some extent in Tangier. A correspondent of the *Novoe Vremya*, of St. Petersburg, sends the startling, but doubtless incorrect, information that there are over two thousand deaths a day from cholera in Pekin. Every precaution is being taken to prevent the introduction of the disease into the Pacific coast ports of this country, and the Treasury Department has ordered, upon the recommendation of the Marine Hospital Service, that the baggage of passengers arriving at any port on the Pacific coast from China, Japan, or Hawaii be disinfected before being landed. A despatch from New Zealand says that there is no cholera at Honolulu, the report of an outbreak there having been started by the death of some Chinamen after eating some poisonous food.

Clinical Instruction at Bellevue Hospital.—At the request of the Commissioners of Public Charities and Correction the members of the Fourth Division of Bellevue Hospital have decided to form an organization for the purpose of giving instruction to graduates and third-year students. The medical staff of the Fourth Division consists of Drs. C. L. Dana, George B. Fowler, and Alexander Lambert. The surgical staff consists of Drs. J. W. S. Gouley, Charles Phelps, and W. F. Fluhrer. The gynecologist is Dr. W. Gill Wylie. The clinics will begin about October 1st. Each course of instruction will continue six weeks, and at least five such courses will be given during the year.

The American Climatological Association will hold its next annual meeting in Lakewood, N. J., in May, 1896. The president of the Association is Dr. James B. Walker, and the secretary Dr. Guy Hinsdale, both of Philadelphia.

The Idaho State Medical Society held its third annual meeting at Boise City on Monday, Tuesday, and Wednesday of this week. The officers for this meeting were Dr. I. H. Moore, of Pocatello, *President;* Dr. E. L. Perrault, of Boise City, *Vice-President;* Dr. C. L. Sweet, of Boise City, *Secretary and Treasurer.*

Suprarenal Extract in Addison's Disease.—Dr. E. Lloyd Jones reports in the *British Medical Journal* of August 24, 1895, a case of Addison's disease treated by extract of suprarenal body. The case was that of a married woman who had been complaining of frequent nausea and vomiting, great weakness, and discoloration of the skin. The first symptoms had appeared about two years before, and consisted in acute pain in the back, diarrhœa, and vomiting. She was placed upon suprarenal extract, and in five days was reported much better, no longer suffering with nausea. At the end of three months Dr. Jones said that she had had no vomiting for a month, she could eat almost any food, the excessive pigmentation had quite disappeared, and she appeared to be practically well.

Vaccination a Preliminary to Marriage.—Couples living in the Scandinavian Peninsula who desire to be married must produce certificates showing that they have been successfully vaccinated, as well as baptized, before the ceremony can be legally performed.

Clinical Department.

CASE OF TRAUMATIC TETANUS WITH URETHRAL SPASM.

By HUGO E. WANGELIN, M.D.,

BELLEVILLE, ILL.

On September 1, 1894, Jacob N——, aged fifty-two, colored, was admitted to the St. Clair County Farm suffering from a nail-thrust in the right foot. About ten days before admittance he stepped on a rusty wire-nail, which penetrated his heavy shoe sole and entered his foot about two inches from the toe and three-quarters of an inch from the medial line of the foot, penetrating to a depth of about an inch. When admitted to the farm he was in fairly good shape. The next day, September 2d, I noticed a jerking of the extensors of the foot and a slight stiffness of the muscles of the jaw. Before night these symptoms became worse, and by the following day had extended to all the extensors of the body, and the jaw was set during the convulsions with the typical *risus sardonicus*. The spasms after the fourth day of admittance were at their height. The slightest touch or breeze blowing over him was enough to bring on the spasms, which recurred spontaneously every five to eight minutes. His whole body was as stiff as a log. He could not bend his arms or his legs. This condition remained several days, and as he was unable to swallow anything, all nourishment was given per rectum. At one time death was expected, but he was safely bridged over by big injections of whiskey.

The second day after admission he was troubled with retention of urine, and I attempted to use the catheter on him. After the metal catheter had entered the urethra about one-half inch it was obstructed in its passage, and no amount of force could introduce it any further. This manipulation caused a convulsion, and when the spasm passed off, the catheter slipped into the bladder very easily. While the catheter was still in the bladder a spasm occurred and so powerfully was the catheter held that it could not be withdrawn. I next attempted to introduce the soft rubber catheter and met with the same results. Waiting till the opportunity offered, I introduced it very easily. While this catheter was in the bladder there was a flow of urine. The spasm was again excited, and the constriction was so great as to stop the flow of urine. This procedure was accompanied with little or no pain, and in fact the only pain the patient complained of was a pressing pain over the region of the stomach. The catheterization was made every day for a week, and each time it was tedious work, but as the case progressed it became easier. In passing the catheter I could detect five distinct points where the instrument would not pass during the spasm. After recovery the catheter would pass easily, and with no amount of search could I find any point along the urethral track where there was an obstruction. Why should this disease act so on the urethra and not on the œsophagus, through which a feeding-tube can be passed even during the spasm?

The first thing done in the treatment of this case was the entire excision of the wound made by the nail and a large crucial incision across the seat of injury. Every two hours the wound was washed out with a very hot solution of 1 to 1000 corrosive sublimate solution, and then packed with corrosive gauze. The internal remedies used were morphia sulph., ¼; bromide potass., grain xx; chloral hydrate, grain xx. This dose was repeated every three hours. When the spasms were great, chloroform was used; during the climax nitroglycerine and whiskey, hypodermically. After he began to mend, the morphia mixture was gradually decreased. At the end of the seventeenth day he was able to leave the ward and was discharged on September 29th as cured.

LOOSE BODY IN THE KNEE-JOINT.

By R. P. MYERS, M.D.,

HONOLULU, H. I.

There appeared in the Medical Record of March 9, 1895, by Dr. Wingelin, an article on "Loose Bone in the Knee-joint." The similarity of the case reported by him to one occurring in my practice in the winter of 1891, in Colorado, U. S., causes me to make the following report:

Mr. C——, a gentleman of leisure, having lived in London some nineteen years, self-indulgent in his appetites, and of a rheumatic diathesis, florid and inert to a degree, occupied all of his time in reading. He told me for some two years he had been suffering much pain in left knee when in motion from having struck the joint; but at the time only suffered slight discomfort. On examination, found no redness, heat, pain or swelling. Upon manipulation, found a loose body floating, as it were, on outside of joint. It was movable to all parts, and at times I would lose it. It would slip several inches above the patella and then I could not find it. I started to operate once and lost it; was not sorry, for I found he could not take chloroform or ether, so I used salt and ice. Located the body, had an assistant apply the "freezing," and arranged to operate, when lo! I found the parts frozen hard and of some whiteness. My chance was gone, and I was annoyed at the condition of the frozen point, and feared results. Some hours passed before the parts regained their normal condition. I kept him in bed the rest of the day, and the following he got up, well rid of his trouble. From that day to the day of his death, which occurred some months after, the floating body could not be found. Could Mr. C—— have knocked off a piece of cartilage when he struck the knee? Through the thin skin it felt smooth and almost compressible. What became of the foreign substance? Did the freezing cause its absorption?

PERIOSTITIS AND NECROSIS OF THE RIBS FOLLOWING TYPHOID FEVER.

By A. S. GRIMM, M.D.,

ST. MARY'S, W. VA.

I was called to see Mr. H—— October 4, 1892, and found him suffering from typhoid fever of a pronounced although not an unusually severe type. There was nothing peculiar about the case until about the end of the third week, when he complained of pain over the sixth rib at the junction of the rib proper with the cartilage. This pain continued, and in a few days a redness with some tenderness was observed over the seat of the trouble, and finally a swelling was distinctly noticed. These symptoms were still present after he was convalescent and able to go around, and after fluctuation appeared (which was two or three months after his recovery from fever) I lanced the tumor and it discharged pus rather freely, which it continued to do for more than a year afterward. After trying in vain to heal the cavity by injecting disinfecting and absorbent washes, I advised an operation, to which he consented, and which I performed as follows:

I made a longitudinal incision over the seat of trouble, and the rib being found necrosed it was excised. It was ascertained that the fifth and seventh ribs were also affected, so the wound was enlarged, and all necrosed tissues were removed by the bone scoop. The wound was closed and dressed with gauze and was not disturbed for several days, when it was dressed again

as before. This was repeated several times until the wound healed throughout the greater part of its length; but it continued to have a small discharge for a considerable time after the operation, which I believe came from the under side of the sternum, as I feared to remove so much of it, although the diseased part appeared to be all removed.

The wound finally healed entirely and the patient (a carpenter) has resumed his work, and is now an able-bodied man.

CONTUSION AND LACERATION OF THE ANTERIOR VAGINAL WALL AND URETHRA.

By FRANK OVERTON, A.M., M.D.,

PATCHOGUE, N. Y.

LATE HOUSE SURGEON, CITY HOSPITAL, NEW YORK.

The literature concerning traumatic injuries of the vagina and urethra of external origin is very scanty. In Keating and Coe's "Clinical Gynecology," page 262, occurs this statement: "The vagina, from its location, is rarely subject to injuries from external violence. There are a few recorded cases in which women have fallen upon stakes that have deeply penetrated the parts, but such cases are very rare." Hence a special interest is attached to a report of the following case involving lacerations of both the vagina and the urethra, with acute distention of the bladder, ending in complete recovery of function.

On February 11, 1895, Mrs. L——, a short, stout Italian, weighing one hundred and seventy-five pounds, aged thirty-two, married, and six months pregnant, fell through a hatchway in the ceiling, striking astride a low bed-post. When seen three hours later the sheets were saturated with blood and she was still bleeding copiously and suffering considerable pain, but there were no signs of shock.

A vaginal examination revealed a soft fluctuating mass bulging the anterior vaginal wall and extending upward as far as the finger could reach. The cervix could not be felt. On everting the labiæ a transverse tear in the anterior vaginal wall was noticed for the first time. This tear split the meatus of the urethra, and extended on each side as far as the posterior limits of the labiæ minoræ. The urethra and the anterior vaginal wall were pushed upward and backward, entirely denuding the symphysis and an inch of each pubic bone. There were no external marks whatever. A speculum and depressor showed the cervix exceedingly high up and normal in appearance. After an hour's attempt at catheterization the urethra was recognized by its cord-like feel, and a soft catheter was finally introduced and over a quart of urine drawn with immediate disappearance of the tumor in the anterior vaginal wall and descent of the cervix.

With only the assistance of half a dozen excited female friends of the patient, and only one basin of a one-per-cent. solution of lysol for the instruments and for antisepsis, the vaginal flap was sewed in place by a continuous catgut suture, and a silkworm-gut suture was inserted in the orifice of the urethra, the end of which was lacerated beyond recognition. The soft-rubber catheter was left in the urethra.

On the next day swelling and ecchymosis appeared in both labiæ and buttocks, which soon became extreme and threatened gangrene. Yet it almost entirely disappeared at the end of ten days without special treatment. The wound was irrigated twice a day with a one-per-cent. lysol solution. Union occurred by first intention without rise of temperature.

Some cystitis developed, and under irrigations of one-half-per-cent. lysol solutions it only increased. The catheter was expelled on the sixth day during an attack of tenesmus, which, however, was not troublesome during convalescence. The cystitis soon subsided and urine was passed about every two hours. At first its flow could not be controlled, but the intervals between urination gradually lengthened until within a month she had recovered almost full control of the bladder.

On May 9, 1895, she was delivered of a fine boy weighing seven and one-half pounds. The scar prolapsed out the way of pressure against the pubic bone, and convalescence was normal.

On July 8th an examination showed only slight remains of the scar. The orifice of the urethra was at the bottom of a slight conical depression surrounded by some small tabs. There were no signs of a stricture of the urethra, and a soft catheter drew off one-half an ounce of urine when introduced an inch. The patient stated that she arose once in the night to urinate, and during the day she urinated about every four hours. She could control the desire to urinate for about ten minutes. The only remaining symptom of the fall was tenderness of the coccyx.

ACUTE TRAUMATIC TETANUS—CHOPART'S OPERATION—DEATH.

By JOSEPH N. BARNEY, Jr., M.D.,

WOODSTOCK, VA.

On Thursday, July 11, 1895, Nettie D——, white, aged twelve, while playing about the kitchen, pierced the ball of the right foot along the axis of first metatarsal bone with a fragment of wood. The splinter was three-fourths of an inch long and slender. She pulled it out and continued running around barefoot. In the evening an elder sister opened a very small abscess at place of puncture, allowing a single drop of pus to escape. This was repeated on Friday and Saturday following. At no time was more than a single drop of pus obtained, and there was almost no pain. Sunday morning the patient found, upon putting on the right shoe, that the ball of the foot was rather tender. For that reason she did not go to Sunday-school, but played around all day. At dinner, Sunday, she complained several times of slight difficulty in mastication. Early upon the morning of Monday, July 15th, she awoke with a feeling of stiffness in the muscles of the neck and difficulty in opening the mouth wide. Upon getting out of bed to go to another room she could only hold the head far back with comfort.

I was summoned at 4.30 A.M., and reached the patient, two miles away, at 6. I found a very stout, well-developed subject; pulse, 90; temperature, 99° F.; respiration, 20. No pain; swallowing good, as regards liquids. Slight convulsive movements of the masseters and temporals; no opisthotonos. The wound of the foot was almost imperceptible and was only slightly tender upon hard pressure. I ordered ten grains chloral hydrate and ten grains sodium bromide every two hours, which was taken with little difficulty.

At 5 P.M. same day returned with my partner, Dr. D. D. Carter, and found the patient had been subject to tetanic spasms since noon. Swallowing was still good. There was marked opisthotonos. The spasms were almost continuous. The patient was perfectly rational and complained of no pain, except a "tired feeling" in the back.

At 6.30 P.M., assisted by Drs. Carter, Boyer, and Ott, Chopart's operation was performed. Some time was occupied in finding and ligating the plantar artery. Time of the operation was fifteen minutes. No exceptional appearance of foot except venous stasis and very dark blood. The patient rallied well, less than one ounce of chloroform having been administered, and never knew up to her death that the operation had been performed, having no pain.

The tetanic seizures recommenced about 8 P.M., and at 2 A.M. Tuesday morning, when I returned, were al-

most continuous. Chloroform had been administered in the interim to the extent of two ounces. Pulse, 150; temperature, 101° F.; respiration, 65. Chloral was increased to 20 grains, and probably five minutes of rest was secured. The condition remained unchanged until 7 A.M., when the laryngeal muscles were tetanized for fully sixty-nine seconds. Under stimulation with brandy she reacted, and shortly after the pulse was 160; temperature, 101° F.; respiration, 90. At 7.20 A.M. she called for water, swallowing with some effort, and said she had no pain. At 7.30 A.M. a tonic spasm of the laryngeal muscle closed the scene, the radial artery pulsating for one and a half minutes after respiration had entirely ceased, and after the pulse had ceased the flexor tendons continued to quiver for thirty seconds. No post mortem was obtained.

CANCER IN HUSBAND AND WIFE.

By E. H. SMITH, M.D.,

SANTA CLARA, CAL.

Mrs. P—— was sixty-eight years of age when I first saw her. Stout and florid. Had always lived very plainly and temperately. She was suffering from the effects of a previous paralytic stroke, which, I have no doubt, was due to an embolus, as there was an organic lesion of the aortic valves. The patient was suffering from gastro-enteric catarrh. She was peculiar, and I could get no history from her except by piecemeal. Last September, nearly a year and a half after first seeing her, I was asked to examine her right breast, and found a very large carcinomatous mass. She had had three abortions, no children at term, and had never had any inflammatory trouble with her breasts. No history of anything specific. This breast broke down, sloughed, and ended in the death of the patient in July.

Mr. E. N. P——, husband of this pa ient, has for years complained of colic pains in the abdomen. He is by occupation a farmer; has always been temperate and has lived a very quiet life. Within the last six months he has developed all the characteristic signs of cancer of the stomach with secondary infiltration of the liver. He has pain and soreness over the stomach and liver; vomits blood and grumous-looking material, and passes bloody mucus from the bowel. The liver is enlarged, extending nearly to the umbilicus, nodular, and tender. The patient is emaciated and very weak; cannot live long. The man is an Irish-American, the woman was a native of Ireland. They were in no way related. No history of heredity on either side can be obtained.

THE ELECTRO-MAGNET FOR THE REMOVAL OF IRON PARTICLES FROM THE EYE.

By S. MITCHELL, M.D.,

HORNELLSVILLE, N. Y.

Under the heading "Accidents to the Eye while Chopping with a Hoe" Dr. W. L. Bullard, of Columbus, Ga., reports three cases where pieces of steel were extracted from the anterior chamber of the eye with iridectomy, and two cases without iridectomy. Also two cases where the foreign body (a particle of steel in both cases) was found in the vitreous after enucleation.

The doctor certainly seems to have met with good success in removing fragments of steel from the anterior chamber by means of forceps. But I should not feel that I was prepared to deal with these cases unless an electro-magnet was a part of my armamentarium, and by its use perhaps save performing an iridectomy as well as removing the offender with greater ease. In those cases where there are strong probabilities that a piece of steel or iron is lodged in the vitreous chamber, a search with the electro-magnet is often rewarded by the removal of the particle and the saving of the globe. And although there may remain no useful vision, it is much better than an artificial eye, and the prospects that it will become a dangerous companion are very slight.

I am now using the Edison incandescent light circuit in my office, and by means of a converter, manufactured by a mechanic in this city, I am able to use it for all kinds of galvano-cautery work. To this converter I attach my electro-magnet and find that it has a much stronger attractive force than with any storage battery that I have ever used.

The electro-magnet is the most useful of all instruments where particles of steel or iron are to be removed from the interior of the globe.

A FAMILY HISTORY OF HYDROCELE.

By R. CADWALLADER, M.D.,

FALL RIVER MILLS, CAL.

It is so rare to find any certain cause for hydrocele of the tunica vaginitis testis that the following family history is worthy of note:

On February 11, 1895, I operated on a double hydrocele in a young man aged twenty-eight. He told me that his elder brother had been treated for the same trouble. On June 12, 1885, I operated on his father for the same thing, limited to the right side, and from him learned the family history.

His father suffered from it for years prior to his death, and of three sons in the second generation two had the trouble. He himself only became afflicted about the time of his discharge from the army in 1865. Of his six sons, two died at nineteen months and three years and six months, apparently free. The third son began to be troubled at fifteen years of age; the fourth son, upon whom I first operated, at sixteen years of age. The fifth son, now seventeen years of age, is apparently free, but a sixth son, who died in infancy, showed a well-marked tumor before his decease. Of the six sons born in the third generation two infants and one adult were normal, while one infant and two adults suffered.

In both cases I opened and excised a large part of the greatly thickened and redundant sac. My experience has taught me not to temporize with injections or tapping.

In cases where the testicle must be removed, and after all castrations, I am in the habit of passing two or three heavy gut sutures, using a full curved needle, from above downward, taking in the layers of fascia forming the canal and the chord, so as to close it for all time. This prevents hernia ever taking place there and controls all hemorrhage from that point. To prevent non-union from the vermicular movements of the scrotum I find continued sutures are better than interrupted ones. Torsion is quicker and better than ligation also when dissecting out the hypertrophied tunica.

Creosote in Pulmonary Tuberculosis.—My own experiments, as also those of Dr. Albu, at the Moabit Hospital, in Berlin, and of others, have conclusively shown that the remedy has no influence upon the disease, and particularly not upon the growth and virulency of the specific germ. Apart from its influence upon the bronchial catarrh, creosote has a value in certain gastro intestinal derangements, but the considerations for its preference are the same as they would be if the patient were not tubercular at all.—Karl von Ruck.

If Patients who abort regularly, and generally before the fourth month, pass the fourth month successfully they will generally go to term.—Parvin.

Society Reports.

THE CANADIAN MEDICAL ASSOCIATION.

Twenty-eighth Annual Meeting, held in Kingston, Ont., August 27, 28, 29, and 30, 1895.

(Special Report for the MEDICAL RECORD.)

Diagnosis and Treatment of Retro-displacements of the Uterus.—DR. A. LAPTHORN SMITH, of Montreal, read a paper with this title. It should be remembered that this condition occurred in single as well as married women; and the condition was not a rare one. It was more common in women who had miscarried. It occurred often among working-girls from overlifting, the bowels being forced between the anterior surface of the uterus and the abdominal wall. Another cause was a fall on the back. The uterus might or might not be held down by adhesions; it often was merely locked down by the prominence of the sacrum. The symptoms sometimes simulated peritonitis, the patient suffering acute pain in the pelvis and back and being unable to pass water, the abdomen being distended and tender; all of which would be relieved by replacement. The doctor then pointed out that the round ligaments contained muscular fibres, and he drew attention to their nerve-supply and functions. During muscular efforts they drew the uterus forward and prevented the intestines from descending in front of it. In women run down in health these little muscles suffered in common with the general muscular system and allowed too much motility of the organ, thus predisposing to the displacement. Other pathological conditions were found associated with this condition—engorgement of the organ due to obstruction of the venous outflow; adhesions, diseased and displaced ovaries and tubes. The patient often suffered much on locomotion and the uterus was tender and painful. Besides miscarriages and abnormal labors as a factor in the causation, the reader of the paper added the use of the pad and binder after labor. The diagnosis was usually easy in emaciated women. The points in the differential diagnosis were alluded to. In an uncomplicated case, by placing the woman in the knee-chest position and introducing a Sims speculum, replacement would follow. If the fundus was locked under the prominence of the sacrum, the anterior lip of the cervix should be grasped and drawn downward and backward; this would free it if there were no adhesions. In cases where adhesions were present he advised the application of Churchill's tincture of iodine to the vault of the vagina and tampons of boro-glycerine. After replacement, the organ may be held in place by a soft-rubber pessary with a special spring. This should be cleansed frequently. The speaker then detailed at length Alexander's operation and that of ventro-fixation for the maintenance of the organ in the correct position, the first being applicable to those cases where the uterus was free, the second to those where adhesions were present.

DR. EDWARD FARRELL, of Halifax, said that in operating for ventro-fixation he had an assistant who held the uterus up with a sound: by doing this a smaller incision would do. In a case he had operated on, four days after the operation she showed signs of intestinal obstruction. The patient was placed in the Trendelenburg position and the hips shaken strongly, when a severe pain announced that the obstruction had disappeared. The bowel was probably pressed between the anterior wall of the uterus and the abdominal wall.

SIR WILLIAM HINGSTON said that in these cases it was not often necessary to resort to an Alexander operation or the operation of ventro-fixation, if patience were exercised. He favored the use of the stem pessary; he preferred the ventro-fixation to the Alexander operation.

Experimental Cachexia Strumipriva.—DR. WESLEY MILLS read a paper on this subject. Before presenting his paper he showed two cats from which he had removed the thyroid glands and a dog from which he had removed one-half the gland. Although the operation on the cats had been done at the same time, yet one showed more advanced symptoms than the other, the latter exhibiting the most resisting power. The cats seemed to be in a sort of stupor, were very much emaciated, although they had been operated on but forty-eight hours before; one of them refused food; in each was seen a tonic spasm when it attempted to perform any muscular exertion; there was considerable dyspnœa, considerable facial movement being noticed at each inspiration. The dog had not suffered nearly so severely and was recovering. The doctor's paper dealt with the various theories given as to the function of the thyroid gland. He dwelt on the difficulty of ascertaining just the exact importance any gland was in its effects upon the blood, on account of the complex composition of the blood. The thyroid had evidently to do with the blood formation; that seemed to be apparent from the fact that the blood became poor in red corpuscles and unduly rich in white ones after the removal of the gland. There was probably a great change in the plasma as well. Recent investigations had shown that the plasma was something more than a fluid in which the corpuscles floated. It had been suggested that the pituitary body, on account of its similarity, had something of the same function as the thyroid; but it was a mistake to suppose that, because they were anatomically similar, their functions were the same. The speaker pointed out that the carnivora were most affected by the removal of the thyroid, the herbivora less, and the rodents not affected at all. Total extirpations in man were rare; in man and in the monkey the result of removal was myxœdema.

Presidential Address.—DR. WILLIAM BAYARD, of St. John, N. B., in his address thanked them for giving him the presidency. The physician's profession, he said, was one of the highest, and instead of its being named last in the learned professions—divinity, law, medicine—it should come second.

When a hospital was a State institution, the doctors should be paid the same as other officials. Every properly organized hospital board should have one or more medical men on it. The philanthropic work of the profession did not stop with the free work it did. It was estimated that sanitary measures in England saved the lives of seventy thousand per year.

In referring to the "cramming" system in schools, he said education should not be pressed to the sacrifice of health. He recommended an investigation into the schools where "cramming" of scholars was carried on. He also said he regarded the use of alcohol as the greatest curse of the age. He pointed out that the medical profession had no representation in Parliament, which was a sad lack to the country as well as to the profession.

In ending a most interesting address, the President recommended the establishment of an institution for inebriates, to be supported by the government, as it obtained the profit from the traffic which caused them.

SIR JAMES GRANT moved the adoption of the address. He said that if the medical profession gave their service to the charitable institutions gratuitously, those who were able to pay should not be allowed to get free doctors at the hospitals. The government should employ someone to carry on the science of bacteriology for the protection of the public. He said that the idea of educating the public up to an university standard, for which they were never intended, was wrong, and that there was too great a tendency at the present age for young farmers to work into the city and

fill up the workshops and professions. Sir James also claimed that the abuse of alcohol could only be banished by education.

Physical Training and Development as a Therapeutic Measure.—Dr. B. E. McKenzie, of Toronto, read a paper with this title. He drew a strong distinction between "athletics," an exercise for sport, and "gymnastics" combined with "massage," being an exercise not only for the development of muscular strength and proficiency in certain lines, but for the improvement in, and often obliteration of, serious deformities. He spoke mostly with regard to the physical training of women, especially those who suffered from muscular or osseous abnormalities. He claimed that the woman of modern times is not to be compared with her ancestor of ancient times in the matter of physical development, and that want practically arose from the evils of modern dress. The speaker asserted that by careful physical training, even those afflicted with spinal curvature may be helped materially, and perhaps entirely cured. He strongly advocated a system of training (by classes, if possible). The patient was to be placed before a mirror, and those muscles upon which the deformities depend are to be brought into forced action according to a graduated system prescribed by the trainer, and the proper position taken. He further said that such treatment invariably tended to aid the functions of all the vital organs, to improve appetite, mental capacity, and all the physiological functions of the body, at the same time increasing the chest measure, height, and weight.

Dr. McKenzie then gave the history of one or two cases treated by gymnastics, one being of a girl of twenty-two with spinal curvature accompanied with pain, in which the treatment was entirely successful; and another of a boy of seven years, with rota-lateral curvature, accompanied by chorea. Complete control of the muscles was gained in less than a week, and entire recovery ensued. He quoted Dr. Crighton Browne as a strong advocate of physical training in muscular abnormalities, who claims that the system is also of benefit to criminals and imbeciles. The speaker concluded with the assertion that the medical profession did not pay enough attention to this subject; that modern methods of living render it imperative, and that the treatment must be used in connection with current approved methods. He also recommended that physical training should be carried on in all schools.

Dr. Louis A. Sayre, of New York, said that the subject of physical training was one of the greatest importance that could be brought before the profession. He was glad to see that it was receiving more recognition than formerly. Physical training was one of the principal elements in the sustenance of a nation. It had a marked effect on the mental and moral force of a people. A good mental condition was dependent on proper nutrition and exercise. The training, he said, must be systematic. He then spoke of the causes of lateral curvature and commended the treatment that Dr. McKenzie had advocated—of mental and physical training, using no instruments, no machinery of any kind, plaster of Paris supports, or splints of any sort. A judicious teacher was necessary to train the children in these exercises. He related the history of a case that had come under his attention, in which the patient, a small boy, weak and frail in body, was mentally an imbecile. Under the treatment the progress, both physical and mental, was exceedingly gratifying. By continuance of the treatment he was sure that the boy would make a useful man.

Dr. Reginald H. Sayre, of New York, said that under this treatment he had found that the life of a child was changed from that of a mere animal to that of a rational human being. To those who had not witnessed the results of the treatment it would be a revelation. He spoke more particularly of the effects of training in certain form of rickets. To properly treat these cases it was absolutely necessary that the physician exercise a very great deal of patience and perseverance. This system of treatment had suffered because of the great numbers of people who had gone into the business who understood little or nothing about it. The effects of proper treatment were particularly noticeable on the muscular, nervous, and circulatory systems. In certain advanced cases where the bones were deformed so that walking was difficult, he advised the use of supports until the muscles, unaided, were strong enough to support the patient. He then referred to the necessity of improvement in school in regard to exercises and gymnastics. He also pointed out the danger of over-training, as was seen in those training for athletic contests.

Dr. Roddick, of Montreal, gave his experience with these cases. In certain cases he had found that, in addition to the training, supports were needed, especially in the intervals between the exercises. He had secured a competent instructress. It was absolutely necessary that this training should be relegated to someone who would perform the duties intelligently. He could speak in the highest terms of this line of treatment in these spinal cases. He said that in the less pronounced cases a cure could certainly be promised. The speaker then entered into a classification of these cases, and dealt with the appropriate form of treatment for each. He said the mistake was often made of developing the muscles on the strong side overmuch and thus aggravating the mischief. He referred to recent observations he had made in Egypt in regard to spinal deformity. He was surprised to learn that they had no cases of this sort there. He believed this was due to the fact that they were in the habit of having the girls carry water-bottles on the head; in this way the muscles of the head and trunk were strengthened. He had introduced this principle in his classes—of having those under training carry weights on their heads as a part of the exercises they perform for the correction of their deformity.

Surgery of the Brain.—Mr. I. H. Cameron, of Toronto, read the address in surgery, taking for his subject "The Present Status of Cerebral Surgery." He pointed out the great strides that had been made in this department of surgery during the past twenty years. He commented particularly on the work of McKeowen. The speaker dealt first with the matter of fractures and their surgical treatment; then with the question of hemorrhage, meningeal and cerebral, and its treatment. The subject of tumors, cysts, and abscesses was then taken up. Some references were then made to the application of surgery to diseased states of the brain.

Sarcoma of the Medulla.—Dr. J. E. Graham, of Toronto, read a paper giving the history of a case of sarcomatous tumor of the medulla oblongata. The patient, a man fifty-two years of age, in active life, contracted typhoid fever, and subsequently la grippe, about a year before the doctor saw him, recovery ensuing in about three months. Some time later, on returning home earlier than usual, he fell on entering the house, bruising his head over the occipital protuberance. There was slight nausea, but ultimate recovery. At a later date the patient showed symptoms of nervousness, irritability, disturbed sleep, failing eye-sight, and an inability to stand alone. The sexual functions were normal. In walking he turned to the left side. His thirst was considerable at times. Still later he experienced numbness of left side of face, neck, and arm, sudden vomiting, hesitation of speech, etc. His sense of touch was normal, as was also his pulse and temperature. There was no muscular atrophy. He complained of headache in the occipital region and pain in the thorax. The treatment consisted in the administration of potassium iodide and artificial foods. Pneumonic symptoms set in at the last, with a rapid consolidation of both

lungs, the temperature rising to 102° F. Death ensued. On post-mortem examination a sarcomatous tumor was found in connection with the restiform body, 5 mm. by 15 mm. in size. The tumor consisted mostly of round cells, with a few spindle-shaped ones interspersed, and was plentifully supplied with blood-vessels.

Dr. Graham quoted many authorities describing somewhat the same condition, showing that the case in question was almost unique. He also showed charts of the position of the tumor.

Removal of the Membrana Tympani and the Ossicles.—This was the title of a paper by Dr. F. Buller, of Montreal. This surgical procedure for the relief of chronic otitis of the middle ear, he said, since its introduction in 1873, had been brought prominently before the profession. It had proved to be a means of benefit in the obstinate cases. He pointed out the difficulties in handling these cases, particularly when the bony structures had become involved in the inflammatory process. The essayist referred to the other methods that had been adopted for the treatment of this condition, particularly to that of clearing out the tympanum through the mastoid. By removal through the external meatus, the method was comparatively easy, and the patient able to go about his work the next day. Even when the discharge recurred there was a much better chance for drainage than before. Antiseptic cleansing measures would be more efficient. Marked improvement in the hearing usually followed this form of treatment, especially where there was no labyrinthine complication. The thickened tympanic structures had become functionless and were better out of the way. The great object in operating was to free the patient from a constant menace to life. The general practitioner and the public were not sufficiently aware of the gravity of this condition. Meningitis often followed the neglect of treatment, and the patient was often mistakenly said to have succumbed from typhoid fever. The doctor then gave the outlines of a few cases showing the beneficial results of this operation.

Skin Clinic.—A skin clinic was conducted by Drs. J. E. Graham, of Toronto, A. R. Robinson and L. Duncan Bulkley, of New York. The first patient was a woman whose hair had fallen out in the spring of 1890, commencing in small areas, and extending. She had consulted a physician who applied croton oil; she was bald for two months. The hair grew again for three months and she had quite a crop; but it fell out again. Various forms of treatment had been adopted, but without avail. During the last year her head was hot at times and covered with perspiration. In his remarks, the speaker said that all the typical signs of alopecia areata were not seen in this case. The diagnostic points he then cited. It appeared to him that there were two classes of cases—the parasitic and the non-parasitic; for he had known of several cases occurring in one household. The pathology was then dealt with. As to treatment, tonics internally; and crysophanic acid and the mercurial ointments were recommended externally.

Dr. Robinson ascertained from the patient that the hair had begun falling out in a small spot, increasing in area by peripheral extension till it reached a diameter of two or three inches. This was characteristic. Examining the scalp with the naked eye, little or no change could be seen. He leaned to the parasitic theory as to causation. Examining the individual hair microscopically, it would be seen to be atrophied. The skin would also be seen to contain inflammatory products, to be seen in the subpapillary layer, and to a limited extent in the epidermis. If a large number of spots was seen, it was an indication that a large amount of scalp was involved, and that cure would not be effected until all the hair had fallen out. Keeping in mind the causation, he believed in bringing the leucocytes into play. Applications of croton oil, fifty per cent., would give a good migration.

Dr. Bulkley, examining the head with a lens, said that small points could be seen, which were broken hairs; these were to be seen among the small finer hairs present. He considered the cause to be trophoneurotic. It might be due to a micro-organism, but not to a parasite; for the patient might rub her head against any other without fear of communicating the disease. With the microscope the diagnosis from tinea tonsurans could be easily made out. Certain forms of seborrhœa attacked the hair similarly, but the absence of inflammation excluded that diagnosis. The prognosis was hopeful, if treatment was continued long enough. With the neurotic theory in mind, he would give nerve tonics—phosphorus, strychnia internally. In addition, he would correct errors in diet, and recommend foods containing fats and phosphorus to supply nutriment to the hairs. Externally he had found application of a saturated carbolic acid solution produce a crop.

A clinic on psoriasis and eczema seborrhœacum was continued, the same three gentlemen contributing.

The Cold Bath in Typhoid Fever.—Dr. William Osler, of Baltimore, read a paper on "Five Years' Experience with the Cold Bath Treatment of Typhoid Fever." He quoted statistics, showing the death-rate to be 6.3 per cent. under this form of treatment, which was considerably less than that obtained from any other method of treatment. Statistics from other hospitals throughout the world agreed with his. The Brandt system he confessed he had not followed fully: Markedly asthenic cases; patients with very high temperature, rapid pulse, meteorism; cases in which severe complications, such as hemorrhage, perforation, pneumonia were present; cases in which the temperature remained under 102½° F.; and mild cases—all of these did not receive the cold bath. In these—fifty-eight cases—the death-rate was 10.2. The effects of the cold bath were not only antipyretic, but beneficial to the system in many ways. The dietary consisted wholly of milk, broths, and egg albumin. The essayist then referred to particular cases, pointing out any special features in the way of symptoms or complications. He outlined, in reply to question, the way in which the baths were given. Many cases of typhoid, he believed, died from over-medication—from too active antipyretic treatment, from too much digitalis, or too much nitroglycerine, or too many doctors.

Dr. W. S. Muir, of Truro, N. S., said that in Truro they had two natural water-courses that had been closed up since the town had been incorporated. But during the fall freshets they had overflowed for three or four days. They rarely had spring typhoid, but in August, following the freshets, they always had an epidemic of typhoid. In every case that had occurred since 1890 he had marked on a map the houses in which the cases had occurred. It was curious to note the line which the typhoid had taken. From that time up till August of this year he had had 159 cases, with a death-rate of 8.1 per cent. In only one single instance could he trace the typhoid to the water-supply. The private practitioner got his cases earlier than his hospital confrère, and thus had a better chance to cope with the disease. He strongly condemned the use of antipyretics. In his experience it was safer to watch the pulse than the temperature. His cases with bad pulses died. He had not yet seen a case of hemorrhage of the bowels die, when the hemorrhage came on early in the second week. Invariably the fatal hemorrhages came on during the third or fourth week.

Operative Treatment of Injuries to the Head.—Dr. McCosh, of New York, read a paper on this subject. The paper dealt first with fractures and their complications, the diagnosis, and appropriate surgical treatment. The technique of the operations was outlined and some interesting cases reported.

Dr. James Sill, of Montreal, spoke of the necessity of early interference in those cases where pressure

symptoms were present. To open the cranium was a comparatively safe operation. It was far safer to operate than not to. Strict asepsis was of the utmost importance.

Dr. George A. Peters, of Toronto, pointed out the necessity of enlarging the wound in cases of punctured fractures, to ascertain whether or not there were any spicules of bone impinging on the brain substance. If the surgeon kept the wound aseptic there was little danger of hernia cerebri. He thought it wise to retain the dura mater wherever possible.

Dr. W. W. White, of St. John, N. B., related the history of several cases that had come under his notice. The first was an operation for depressed bone in a coal-heaver who had been struck with a piece of coal. The doctor used a chisel and mallet in operating. Perfect recovery ensued. He also related the case of a child that had received a fall followed by paralysis of the right side, accompanied with loss of speech, the dumbness lasting six months. Relief followed the absorption of the clot.

Address in Medicine.—Dr. Edward Farrell, of Halifax, delivered the address in medicine. The address dealt with the wonderful advancement that had been made in recent years in the various departments of medicine. He outlined the advances that had been made in clinical medicine and morbid pathology, as well as in the more recent study of bacteriology. He pointed out the immense saving of life effected by the study of sanitary science. He spoke particularly of the names of men eminent in medicine who had worked all their lives in the investigation of epidemic diseases, and through whose influences these scourges of the human race were becoming things of the past. He held that states were not lavish enough with grants for the furtherance of scientific research, particularly those of English-speaking peoples.

New Remedies in Dermatology.—Dr. L. Duncan Bulkley, of New York, read a paper on the newer remedies in skin diseases. Among those used in local treatment he referred more particularly to the value of resorcin, ichthyol, europhen, aristol.

Mechanical Dysmenorrhœa.—Dr. J. Campbell, of Seaforth, read a paper on dysmenorrhœa, accompanied by anteversion of the uterus and stenosis of the os internum. He outlined the treatment as being first, rapid dilatation with applications to the endometrium, afterward with galvanism, followed by laparotomy with extirpation of both tubes and ovaries; a complete cure resulting. The ovaries on removal showed a cystic condition which seemed to be the only element to account for the symptoms of the dysmenorrhœa which persisted after the dilatation.

Early Treatment of Skin Cancer.—Dr. A. R. Robinson, of New York, read a paper on "The Importance of Early Treatment in Cutaneous Cancer." The doctor pointed out and illustrated with drawings the pathological condition present in the varied classes of epithelial growths, and showed the relation the progress of the clinical symptoms bore to the pathological condition, from a study of which rational treatment could be decided upon. Cancer was, he contended, at first purely a local disease and quite amenable to cure if removed before the deeper structures were involved. In the cure of these cases the essayist said that he never used the knife. He condemned strongly the usage of applications of nitrate of silver to small growths of a suspicious character. This often only aggravated the mischief.

Thyroid Feeding in Stupor.—Dr. C. K. Clarke, of Kingston, read a paper on this subject. He had observed, as had been done before, the effects of acute disease on these cases of stupor, how that it benefited them—in some cases effecting a complete cure. In the first case reported the patient was almost a hopeless dement. Upon the administration of the thyroid extract improvement began, which gradually progressed until the cure seemed to be next to complete: when suddenly the patient, without apparent cause, relapsed back completely into his former condition. In several other cases which the doctor reported the effects were well marked, a permanent cure resulting. The doses given went as high as twenty grains.

Hip-joint Disease.—Dr. Lewis A. Sayre, of New York, then gave a clinic on "Hip joint Disease." Two patients were shown. Dr. Sayre showed how he conducted the examination of a patient suffering from this trouble. The patient was completely stripped from the chest downward, and two tapes were applied to the front of the body, the one reaching from the ensiform cartilage to the pubis, the other joining the anterior superior spinous processes. These had to be kept at right angles. It was found that, with the spine held well down to the hard table, that the sound leg could be tilted and turned in any direction without tilting the pelvis, the sick limb being held flexed to such a degree as to allow the back to be kept flat. Upon then attempting to straighten the leg the diseased side of the pelvis would tilt up. It was shown that while slight traction was made in the line in which the limb was, when flexed to be comfortable, that ease was at once experienced. This indicated the line of treatment—to fix the joint so that the leg would be held in this position and to make slight traction. Then to gradually straighten while the child remained on his back. At the end of two or three weeks, when the limb was straight, a fixation splint could be applied and the child allowed to get out into the open air. This was the method to pursue if suppuration and abscess had not set in.

Acute Uræmia.—Dr. McPhedran then read a paper on "Acute Uræmia, Followed by Gangrenous Abscess of the Lung." The patient, a man aged fifty-eight, had for some time been failing in health, the manifestations of the decline being shown by vertigo, frequency of micturition, constipation, disagreeable taste in the mouth, hard pulse, etc. He had a convulsion, sudden in its onset and severe in character. It was followed by prolonged coma. The second week after it was noticed that his breath was very foul, and his sputum showed the presence of elastic fibres. Albumin was present in large quantity in the urine. Signs of change in the lung were noted by physical examination. There were recurring attacks of hemorrhage, and at three distinct periods the breath smelled gangrenous. Under treatment improvement took place, followed by recovery. The condition of the lung the reader believed to be due to degeneration of the pulmonary artery primarily. Beside the hygienic treatment diuretin was administered in 15-grain doses every four hours.

Ophthalmometry.—Dr. R. A. Reeve read a paper in which he pointed out the great value of the ophthalmometer in ascertaining the presence of astigmatism and other refractive errors. He showed the superiority of this instrument over other appliances formerly used. By means of a photograph he demonstrated the parts of which it was composed.

Tumor of the Brain.—Dr. J. Webster of Kingston

creased glandular secretion. Leucocytes attacked the gonococci, carried them to the surface, where they were discharged, and repair took place and the symptoms subsided. Resolution took place slowly in the urethral glands, which continued to discharge some time after the inflammation in the remainder of the urethra had subsided.

Posterior Urethritis.—Dr. Guiteras considered this as an extension of the disease: some thought it occurred in eighty per cent. of the cases, and he thought it occurred at least that often. Often it was not severe enough to cause symptoms and was not noticed. The disease did not travel down the urethra fast, for the mucous membrane was less vascular and almost void of glands and follicles. The patients in whom marked symptoms occurred were those who were physically be-

mucus, and blood. About three weeks after labor came on. The uterus was almost entirely filled with a spongy, friable placenta, which was removed piece-meal. Several of the pores contained hydatids. The fœtus was dead and crushed flat. The woman made a good recovery.

Hernia of the Appendix.—Dr. R. W. Garratt, of Kingston, related the history of a case of hernia of the vermiform appendix. The condition occurred in a green-grocer who had much heavy lifting. After a heavy lift he had taken some five years previous, he discovered that there was a tumor in the left inguinal region, which gave him considerable pain. He underwent treatment by truss for some time, but without satisfaction. It was thought to be omentum, and an operation was finally decided upon. Upon cutting down on the tumor a bubble of gas was noticed issuing from it, followed by the exudation of about a drachm of stinking pus. The appendix was drawn down and removed. The patient made an excellent recovery.

Nephrectomy.—Dr. Ahern, of Quebec, reported a case of "Transperitoneal Nephrectomy." The operation was done for hydronephrosis. The trouble began by the appearance of a tumor in the left side, which after a few weeks disappeared. It was accompanied by pain. The tumor reformed. The history of the case and the points of the differential diagnosis were pointed out. A distinguishing point in the diagnosis was the palpation of a ribbon-like band over the surface of the tumor—the descending colon. The tumor was removed by an anterior median incision; the condition was found to have been due to a congenital malformation of the ureter. These cases usually occurred on the right side. The essayist referred to the treatment of these cases by aspiration and by nephrectomy.

Dr. C. R. Dickinson, of Toronto, read a paper on "Some Indications for Electrolysis in Angioma and Goitre." He pointed out that by treating angioma by this method the chances of disfigurement were much less than by other measures. Excision was often useless, the cautery was sometimes disappointing, and scarifications, applications, and injections were not free from danger. Small, superficial angiomata called for the negative pole and mild currents. In the cavernous form destruction of tissue might be called for. Histories of cases were given showing the good results following this form of treatment. The doctor also spoke of its application to goitre, one hundred and twenty cases of which he had treated with gratifying success.

The Canadian Militia Medical Service.—A paper was presented by Dr. W. Topin, of Halifax, on changes which he proposed in the Canadian Militia Medical Service, the substance of which was that, in the speaker's opinion, instruction in military surgery should be given to militia medical officers. He also held that the ambulance system should be reinforced by bearer companies, where it was possible, on the basis laid down by the Deputy Surgeon-General to render first aid to the wounded and assist in field hospitals.

hair had begun
in area by peripheral extension till it reached a diameter of two or three inches. This was characteristic. Examining the scalp with the naked eye, little or no change could be seen. He leaned to the parasitic theory as to causation. Examining the individual hair microscopically, it would be seen to be atrophied. The skin would also be seen to contain inflammatory products, to be seen in the subpapillary layer, and to a limited extent in the epidermis. If a large number of spots was seen, it was an indication that a large amount of scalp was involved, and that cure would not be effected until all the hair had fallen out. Keeping in mind the causation, he believed in bringing the leucocytes into play. Applications of croton oil, fifty per cent., would give a good migration.

NEW YORK COUNTY MEDICAL ASSOCIATION.

Stated Meeting, June 17, 1895.

Samuel B. W. McLeod, M.D., President, in the Chair.

Repeated Intestinal Anastomosis on a Dog.—Dr. Thomas H. Manley presented some specimens from a dog on which, at intervals of about two weeks, he had performed intestinal anastomosis four different times, with complete success.

O'Hara's Operation for Hernia.—Dr. Manley then presented a child with inguinal hernia, and made some remarks upon the radical treatment of this affection by the O'Hara or Australian method. (See p. 366.)

State Medicine: The Physician as a Citizen.—Dr. Douglas H. Stewart read a paper with this title. He thought the medical profession was without influence in public affairs, because, unlike the legal profession, it was not organized to act politically. About the only public office held by physicians related to the Health Board, and even there the law expressly stated that the president should not be a physician. What would the legal profession say of a law which forbade a lawyer being a judge of the Supreme Court? We allowed outsiders to do our thinking for us in public matters, and they rather despised us for allowing them to do it. Our lack of unity made us the mark of caustic sarcasm. But every man would become a giant if it was known that his whole profession was at his back. One for all, and all for one, would win recognition and respect every time and everywhere. Perhaps our most powerful disorganizers were the hospitals and dispensaries outside of the public charity institutions. They made an annual report showing a wonderful number of patients treated, claimed a small death-rate and remarkable results, but there was no mention of the number of dying patients refused admittance or transferred to Bellevue. If the members of the medical profession would decide not to allow their learning and time to be taxed without adequate representation on the Board of Trustees, the medical charity evil would soon be mitigated and the lay trustee would cease his arrogance.

Another field in which a united medical profession could do something to reform abuses, related to the condition of the streets. London and Paris, which had a much larger street area than New York, were kept, by comparison, immaculate. Then our uneven pavements were being constantly dug up and left so for days. The stones were put back loosely, to be sunk immediately far below the surrounding level. The physician was more interested in good roads than the farmer and merchant, as he could not, like them, wait for fair weather. Here railroad magnates still used horses which distributed manure in the streets; they added salt to our slush; they compelled us to hang on a strap. A little agitation for a law, "No seat, no fare," would remedy the latter evil. We were compelled to support the insane of the State while supporting our own. In our public schools many rooms were without seats, and our children had to sit on the floor; in some the seats were too small, causing crooked spines; in some, three children had but two seats between them; others were dark and alongside the elevated railroad and noisy streets; one school for boys was made use of for girls, and as the urinals were inconvenient, the ingenious janitor bored holes into the floor and allowed the cellar to become flooded. There were many schools without sewer connections.

In our progressive city the sick were prescribed for by [illegible] doctor who never saw them. Our
the lithotomy posture, the vagina opened with an anterior and posterior retractor, and the vagina thoroughly painted with nitrate of silver, twenty to thirty grains to the ounce. The vagina was packed with iodoform

pense in Cincinnati, St. Louis, New Orleans, and various other cities, and found to give off such a horrible stink for many blocks around that it had to be abandoned. Here they had put up a temporary, most defective incineration plant on trial, and had condemned it, when the method properly carried out in other cities had given the highest degree of success. Other cities put such matters into the hands of the Health Board. Physicians were so far from being united that they would go into court, at the instigation of some shyster lawyer, and testify against one another. Let us act together. Let us back a man sometimes, because he is a brother. Carry this fact in mind, that not fifty-five per cent. of medical service in this city is paid for. Let us do what we can to take our city out from under the heavy rule of Albany.

The paper was discussed by Drs A. B. Deyxard, Frank Van Fleet, G. D. McGauran, C. B. White, Brothers, T. H. Manley, Nye, and the discussion was closed by the author. They spoke warmly against the abuses mentioned, as well as others, and advocated greater unity in the profession, and participation in public affairs.

Living Greek: The Language of Physicians and Scholars; a Language Easily Acquired.—Dr. Achilles Rose read the paper. Since the establishment of the American school at Athens, founded in 1892 by the American Archæological Institute, supported by contributions from eighteen universities in the United States, there had been a diffusion among cultivated people of a more correct notion of the Greek language, and of the fact that it was a living language. It was generally conceded that a study of the classical languages, and of the Greek especially, was a powerful means of elevating and ennobling the mind and character, and could not be dispensed with. The Greek language was practical as well as ideal. It was easy to learn as a living language, but it was necessary to reform methods of teaching it in the colleges. It was remarkable how it had been calumniated, by claiming that, as spoken by the Greeks to-day, it was mixed with various other languages. As a matter of fact, it had been preserved remarkably pure from ancient times, and for this we were much indebted to the Greek Church. As an example of the ease with which Greek could be learned as a living language, Dr. Rose presented his little daughter, about seven years of age, who recited a piece and sang in Greek. She also spoke a piece in French, showing that during childhood the learning of languages was easy.

Dr. Fred. C. Valentine thought it would prove far more practical to make Spanish the language of physicians and scholars, for it was already spoken by eighty millions of people, was beautiful, its orthography was phonetic with few exceptions, and one could learn to speak it in as many weeks as were required to learn the Greek alphabet.

The President had come to the conclusion that the preponderance of evidence was in favor of Greek as the language of scholars, for it was a language of very great beauty, of very great flexibility, and one possessing the power to carry ideas to others as perhaps no other language could.

to the lowest[illegible] of the urethra.

Hospitals for Tuberculosis.—At the recent meeting of the American Climatological Association it was noted that, "Since tuberculosis has been demonstrated to be a communicable disease, it has become doubly desirable that hospitals for the reception of the poor afflicted with the disease should be established," and the Association resolved to "recommend the establishment of such hospitals in every State, not only for the relief of the great suffering attending this disease among the poor, but also as a protection of the community against its spread."

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, Monday Evening, May 27, 1895.

Egbert H. Grandin, M.D., President, in the Chair.

Dr. S. Tynberg exhibited the case of pygopagus (joined twins) which has been previously described in the Medical Record.

Gonorrhœa in Man.—Dr. Ramon Guiteras read a paper on this subject. He said gonorrhœa was derived from γόνος, semen, and ῥέω, to flow; as it was for a long time considered a disease of the secretory apparatus resulting in a flow of semen from the urethra. The more proper name urethritis appeared to be gaining ground. The disease had been prevalent since the earliest days of medicine, mentioned by Hippocrates and Celsus, and considered contagious.

About the last of the fifteenth century syphilis became prevalent in Europe, and was considered related to gonorrhœa and due to the same virus. This idea prevailed until the Revolution, when John Hunter claimed they were two distinct diseases. He inoculated himself with pus from an acute urethritis, but the patient had an unrecognized syphilis at the same time. Hunter contracted it, was convinced that both were the same, and thus the true relation was undiscovered until Ricord's investigations.

Etiology.—Usually due to coitus. Rarely to indirect causes. Two varieties were spoken of which he would call urethritis and pseudo-urethritis. The first embraced the acute running clap due to the gonococcus of Neisser, the latter the so-called "strains" and slight ephemeral discharges. The period of incubation was one to fourteen days, and the discharge was generally noticed about the third day.

Clinical History.—Shortly after a suspicious coitus there was itching sensation about the meatus, followed by pain during micturition, slight moisture, or drop of muco-pus on meatus, which was somewhat congested. These symptoms grew more severe steadily for one or two weeks and gradually subsided. The course of an acute attack was from four to five weeks. When it passed six weeks it was considered chronic.

Diagnosis.—The microscope, or a few days' time, would distinguish between urethritis and pseudo-urethritis. The former grew rapidly worse, the latter rapidly better. The former was more difficult to distinguish from an acute exacerbation of an old condition, where the gonococcus was always present. The history of the cases usually assisted.

The chancroid ulcer and chancre might be confused with urethritis. The former could be recognized by the loss of tissue. In the latter, where there was difficulty in opening the meatus to see, he found a wire nasal speculum an excellent aid.

Pathology.—The gonococcus made its way to the subepithelial tissue and excited an inflammation, there was an exfoliation of the urethral epithelium and increased glandular secretion. Leucocytes attacked the gonococci, carried them to the surface, where they were discharged, and repair took place and the symptoms subsided. Resolution took place slowly in the urethral glands, which continued to discharge some time after the inflammation in the remainder of the urethra had subsided.

Posterior Urethritis.—Dr. Guiteras considered this as an extension of the disease; some thought it occurred in eighty per cent. of the cases, and he thought it occurred at least that often. Often it was not severe enough to cause symptoms and was not noticed. The disease did not travel down the urethra fast, for the mucous membrane was less vascular and almost void of glands and follicles. The patients in whom marked symptoms occurred were those who were physically be-

low par. It might occur any time during the attack, but usually not before the tenth day, and most generally in the third or fourth week. The patient experienced discomfort and a sense of weight in the perineum, increased frequency of urination, and in severe cases urinated every few minutes during the day and often at night. When subacute the Ultzman glass was used for diagnosis.

Chronic Urethritis.—This condition was considered to exist when after six weeks some discharge existed, but so slight that no discharge was noticed during the day and only slight in the morning. "Tripper faden" were usually found, and this was generally due to the presence of granular patches, ulcerations, denudations, localized hyperæmia, or strictures along the urethra.

Experience had taught him the majority of cases were due to strictures with localized congestion posterior to them. The strictures were due to localized inflammation and were soft, resilient, or hard. There was another form, the congenital, which was located near the meatus and was very unyielding.

He examined the patient for chronic urethritis as follows: the meatus for a discharge which would point to anterior inflammation, washed out the anterior urethra with a rubber or glass tube, then let the patient pass his urine in two glasses. If the first glass contained more flakes than the second, he concluded there was posterior urethritis, and if there were no flakes in either it was evident there was no posterior trouble. He then examined the urethra with the acorn bulb bougies for strictures, and then endoscoped the urethra for granular patches, localized congestions, denudations, or ulcerations.

Prognosis.—The disease usually lasted from four to six weeks. It was considered cured when the discharge ceased, but it might remain localized or subacute after this. Some authors held that as long as "Tripper faden" were found the disease was not cured. Dr. Guiteras said he presumed they were right, but he thought they would disappear if the patient abstained from alcoholism and venery for a few weeks. The occurrence of posterior urethritis, complications, or strictures made the prognosis difficult.

Treatment.—Dr. Guiteras said that in his own practice the treatment depended on, 1, the stage of inflammation in which the patient presented himself; 2, the presence or absence of posterior urethritis; 3, the presence or absence of strictures.

If the patient had an acute attack in the first stage with great tenderness, he delayed active treatment for a while and tried to make him comfortable. He gave him a diluent; put him on either cubebs in teaspoonful doses three times a day, or santal midi capsules, beginning with one and running up to four three times a day. He regulated the bowels with Rochelle salts, prescribed two hot sitz-baths a day, and regulated the diet.

This usually took away the congestion in three days, enough to permit of hand astringent injections or hot irrigations. He then began with irrigations given once a day, accompanied by mild slightly astringent hand injection. If the patient were in a hospital he used irrigation twice a day and no hand injection. For irrigation he used permanganate of potash or nitrate of silver. He used to begin with permanganate of potash, and used silver only when the former failed; now he reversed it, for the nitrate of silver seemed to have the best effect. If the permanganate were used he began with one in five thousand and increased to one in two thousand, and if nitrate of silver, he began with one in eight thousand and increased to one in two thousand. The irrigating fluid should be used as hot as could be borne. In posterior urethritis he did not use hand injections, but modified his method of irrigation by increasing the height of the douche jar from two to five feet. If the solution did not overcome the "cut-off" muscle he directed the patient to strain as if to urinate, and then to take a few deep breaths. To his internal treatment he added ten drops of belladonna three times a day to overcome the tenesmus, and sandal-wood oil to modify the urine. Of the latter he began with fifteen drops, and increased five drops a day as long as it was well borne. If irrigation did not benefit he left off the general treatment of the urethra and gave posterior instillations of nitrate of silver every other day by means of the Ultzman syringe, beginning with one grain to the ounce solution and gradually increasing.

In chronic urethritis he examined for strictures with a bulbous sound and endoscoped the urethra. If there were yielding strictures he dilated them by the Oberlander dilator by easy stages, and afterward passed the Otis curve anointed with equal parts of the ointment of the red oxide of mercury and vaseline. If the stricture were unyielding he advised urethrotomy by the Otis method.

Dr. Guiteras said that in closing he wished to call attention to the fact that patients would complain as much of a one to one thousand solution of nitrate of silver by the irrigation method as they would of one in fifty solution by the hand method.

The Treatment of Gonorrhœa in Women.—Dr. William R. Pryor read the paper on this subject. He said that throughout the entire treatment of gonorrhœa in women one principle must govern the physician; the disease must be locally checked and extension prevented. Gonorrhœa produced few destructive lesions when it affected primarily the external genitals, but when it had extended to the pelvic viscera it often destroyed the integrity of the affected organs and chronic invalidism might be induced.

Gonorrhœal Urethritis.—This should be treated from the very first. Internally he administered citrate of potash for the first three days or so, to alkalinize the urine, locally he applied every day nitrate of silver, 10 grains to 1 ounce, and after the urethritis had somewhat subsided the solution might be reduced to 5 grains to 1 ounce, and applied less often. The patient should frequently bathe the vulva with one-half per cent. lysol solution; but no douching was admissible.

Gonorrhœal Cystitis.—Forty to sixty grains of benzoate of soda should be given internally, the bladder should be washed out with super-saturated solution of boracic acid at least twice a day, the bladder being filled and emptied several times at each sitting. The viscus should then be left full of the solution. The accompanying urethritis should be treated with daily application of nitrate of silver, 5 grains to 1 ounce. In washing out the bladder a single catheter should be used.

Gonorrhœal Ureteritis.—If the bladder were affected acutely at the same time, benzoate of soda only should be used, but if the bladder were not very sensitive the ureter might be washed out with boracic-acid solution. When the infection attacked the urinary system it could not be guarded against by antiseptics, but the urine had to be rendered antiseptic and increased in quantity by the use of large amounts of Buffalo Lithia water.

Gonorrhœal Vulvitis.—Nitrate of silver should be applied to every fold of the vulva, meatus urinarius, clitoris, and nymphæ, and every part be painted with a solution of twenty grains to the ounce and allowed to dry. The vagina should be packed with twenty per

[illegible], in some, three children had but two seats between them; others were dark and alongside the elevated railroad and noisy streets; one school for boys was made use of for girls, and as the urinals were inconvenient, the ingenious janitor bored holes into the floor and allowed the cellar to become flooded. There were many schools without sewer connections.

In our progressive city the sick were prescribed for by a newspaper doctor who never saw them. Our Street Cleaning Department seemed on the eve of adopting the reduction process for the disposal of refuse, a method which had been tried at great ex-

gauze, the application repeated every two days for three treatments when the gauze alone could be used.

Gonorrhœal Endocervicitis.—Dr. Pryor said this was about five times as frequent as vaginitis and too much neglected. The mucous membrane of the cervix should be touched with a strong tincture of iodine, repeated every day, and the vagina packed with iodoform gauze. Care should be taken not to pass the internal os, and as the cervix was lined with true mucous membrane it would take quite a little while to cure the patient. As there was no possible way to place a dam between the infected locality and the more important structures above, the only hope was to successfully treat the affection by such means as were efficiently germicidal and still do the least amount of damage to the tissue cells, upon whose resistance to pathological influences depended protection against complications.

Gonorrhœal Endometritis.—Immediate operation was necessary. If the cervix was not dilated, dilate it up to one-half inch, and if this was not possible, incise it. Dilate the uterine canal, wash with boric acid solution, using a large Jirtsch-Bozeman catheter. The cervix was then swabbed with five per cent. carbolic solution, and the uterus thoroughly curetted. All débris was then washed out with the irrigating catheter, but no bichloride, carbolic, or other strong antiseptic should be used, for they would produce sloughing and a nidus for any gonococci which might remain. He did not paint the endometrium with iodine or carbolic acid. He then packed the uterus with iodoform gauze, also the vagina, and the first dressing was made in five days. He based his technique upon the belief that the endometrium was a lymphoid structure, and any agent strong enough to prove germicidal would destroy the living body cells.

Dr. Pryor did not favor palliative treatment of gonorrhœal endometritis. He believed no case of gonorrhœa was cured as long as the gonococcus was found, and it was the physician's duty to impress upon the patient the importance of persistent treatment at his hands. He believed the prevalence of gonorrhœa was due more to the uncured form in women than to the gleet of men. Gonorrhœal salpingitis in the acute form was treated in the same manner as gonorrhœal endometritis, but in the chronic form nothing but extirpation of the tubes would effect a cure.

When to Begin and when to Stop Treatment.—Dr. Herman Goldenberg opened the discussion. He said there were two questions: first, when should treatment be begun, and second, when should it end. It seemed natural to attack the gonococcus so as to kill it. It entered the tissue before the third day, so he did not see how nitrate of silver could cure unless used within a few hours. He had found only one case that yielded to the primary treatment, and he believed most of the cases cured thus were exacerbations. Permanganate of potassium had proved the most satisfactory to him. Posterior urethritis had been considered a complication, but now it was admitted to be an extension, and in thirty per cent. of the cases there was a posterior urethritis by the twelfth day. There were cases that could not be cured, but fortunately they were few. Neisser depended upon a microscopic examination, but he thought in cases where matrimony was contemplated the condition of the prostate should [illegible]

Hospitals for Tuberculosis.—At the recent meeting of the American Climatological Association it was noted that, "Since tuberculosis has been demonstrated to be a communicable disease, it has become doubly desirable that hospitals for the reception of the poor afflicted with the disease should be established," and the Association resolved to "recommend the establish[illegible]

Alterative.—Alterating drugs—such as salts of arsenic, copper, zinc, and iron—should usually be given directly after food, except where local conditions require their administration in small doses before food.

catarrhal one, but a severe form. The urethra might recover after one attack, but after more it never recovered. The whole question of chronic urethritis was summed up in the one word ulcer. This might be microscopic, but situated along the narrow sinus it would exist for a long time. By the thickening of the tissue strictures were formed, but they were rare and seldom found at autopsy. The ulcer would stop the sound and the patient was told that he had an ulcer. Nitrate of silver was used, for it excited a slight inflammation which brought the cells to the surface and the ulcer was reached. He thought it was the exception where posterior urethritis was not found.

A New Culture Medium for the Gonococcus.—Dr. Fred C. Valentine thought the first author erred in thinking the name urethritis was becoming more used than gonorrhœa, and he feared the latter name would be continued. It was strange that Dr. Guiteras would use a wire nasal speculum when he could use Oberlander's urethroscope. Dr. Guiteras had mentioned six weeks as a normal time, but Janet, of Paris, allowed two days, and his own cases lasted five days. He thought Janet's theory, that the permanganate of potassium injection caused an anæmia and prevented a good culture medium for the gonococcus, was the right one. Dr. Valentine said he had found a good culture medium for the gonococcus in sandal oil. There was one thing which could be positively stated, no man should be allowed to marry who could infect the woman. By treating the urethra with nitrate of silver and examining the exudate, it could be determined whether the gonococcus was present or not.

Dr. J. P. McGowan said that at their clinic they used warm solution of permanganate of potassium and gradually increased the solution. The bladder might be filled with the solution. The patient was often relieved in a few hours and should be treated two days. [illegible] which a rest is grateful. The usual exodus has taken place and London is said to be empty, but there are plenty of doctors for all the requirements of the public, although so many are taking their holidays. Every one of the staff of reporters who worked so assiduously for the Medical Record at the meeting disappeared immediately afterward, and some of them carried their especially if used strong.

Infection in the Puerperal State.—Dr. H. N. Vineberg said he was sorry the writer of the paper did not mention infection during the puerperal period. There was no doubt that cases occurred, and he had seen two such. He thought that as long as a gonorrhœal affection was limited to the cervix, it should be treated in a way that it would not be extended, for the disease would not go beyond the internal os by itself. The reason the disease advanced rapidly sometimes was because some other disease was present, or the treatment extended it instead of stopping it. He approved of the excision of Bartholoni's glands when they were infected, but it was not as easy an operation as might be thought.

Dr. Herman L. Collier said the patients came to the physician at different stages of the disease, and he had to treat them according to the stage. It was possible to cure ten per cent. of the cases in the acute form in two weeks. To render relief, at first cooling lotions were advisable, as opium wash, etc. For the second stage, nitrate of silver was satisfactory. He coated the vagina with a solution of nitrate of silver and the outside with a ten-grain solution. This might be done every day or every other day. Douching every four hours with ammonia solution or some other was important. When the disease extended to the endometrium it was generally the result of carelessness.

Dr. Ramon Guiteras said, in closing, that the reason he used the wire nasal speculum was that he could examine thoroughly and easily the anterior half-inch of the urethra, and that was all he wanted when

he used it. There was a difference of opinion as to the length of the disease. Dr. Finger had said six weeks. He thought ten grains of nitrate of silver to the ounce was too much.

Therapeutic Hints.

Salicylates in Rheumatism.—The salicylate acid must be obtained from the vegetable kingdom; it must be given without an alkali or a base; from forty to eighty grains should be given daily for ten days; the patient's diet should consist of milk and farinaceous food for at least a week; the bowels should be freely opened daily.—LATHAM.

Dyspepsia.—In every case of persistent dyspepsia, careful examination of urine should be made.—LOOMIS.

Constipation in Infants.—

Iodine,
Iodide of potassium ..... āā gr. vj.
M. Sig.: Apply to lesions.

—MARFAN.

For Eczema of the Face.—Carefully remove all the crusts. Avoid water. Keep the following ointment constantly applied to the lesions by means of a soft linen mask.

℞. Ung. Picis ..... ʒ i.
Ung. Diach ..... ʒ ij.
Ung. Zinci ox ..... ʒ ij.
Mix. Sig.: For external use.

Treatment of Cardiac Disease.—In strychnine we have an ideal cardiac stimulant, which not only acts upon the circulation, but as well upon respiration, digestion, and assimilation. It is especially indicated in the weak heart of pneumonia and febrile processes, given hypodermatically in $\frac{1}{30}$ to $\frac{1}{15}$ grain doses, repeated until some sign of the drug is manifested. It is also useful to relieve the alarming symptoms which occur in surgical anæsthesia, in the cardiac weakness often associated with neurasthenia, and in that due to depressed nerve-force. Strophanthus is of great value as a cardiac sedative in that form of tachycardia so common in exophthalmic goitre. These two drugs will retain their supremacy because of their influence over the vital centres in the medulla, to which the various systems of the body look for support and encouragement.—KRAUSS.

Hepatic and Nephritic Colic.—

℞. Valerianate of amyl,
Sulphuric ether ..... āā gtt. iij.
M. For one capsule. Let twenty such capsules be made.
Sig.: Two capsules every half hour until six have been taken.

Leucocytes in Diphtheria.—1. The leucocytosis of diphtheria is materially different from that of the other infectious diseases which have been investigated in that particular. 2. Hyper-leucocytosis is in diphtheria a distinctly unfavorable sign, and, consequently, valuable indications as to the progress of a case and the efficiency of any particular plan of treatment may often be gained from examination of the blood. 3. The diphtheria bacilli which find their way into the body are destroyed by the phagocytic action of the leucocytes. 4. The majority of the diphtheria bacilli concerned in the production of the lesion of diphtheria are cast off in the false membrane: only a very small number are disposed of by phagocytosis. 5. The action of the poison of diphtheria in inducing necrosis of cells tends to lessen the power of the leucocytes to act as phagocytes. 6. The action of antitoxic serum is to make all the cells of the body more resistant to the destructive action of the diphtheritic poison.—GABRITSCHEWSKY.

Asthma.—At the moment of the attack, spray rapidly the back of the patient with chloride of methyl, from above downward and from below upward. The attack will cease in a few moments; if not, spray lightly the upper part of the chest. If the skin be delicate, as in women, cover the parts with a bit of fine gauze and make the strength of the spray proportionate to the strength of the patient and the violence of the attack.—TSAKIRIS.

Chronic Constipation.—

℞. Strych. sulph ..... gr. i.
Ext. bellad ..... gr. v.
Pulv. ipecac ..... gr. x.
Ext. calocynth co ..... gr. xv.
Pulv. rhei ..... gr. xv.
M. div. in capsulæ No. XXX.

Tic Douloureux.—Treatment consists in making subcutaneous injections of the following solution into the affected side of the face: Distilled water, 10 grammes (2½ fluidrachms); antipyrin, 4 grammes (1 drachm); hydrochlorate of cocaine, 0.03 gramme (½ grain). The face sometimes became much swollen, but soon resumed its normal appearance.—GRANDCLÉMENT.

Diarrhœa in Infants.—For diarrhœa in infants from one to two years of age, the following is useful:—

℞. Acid. carbolici..... gr. ij.
Bismuth subnit..... ʒj.
Syrup acaciæ..... ʒss.
Aq. menth. pip..... ad ʒij.
M. ft. mist.: A half teaspoonful every two to four hours.

Not to be Given During Pregnancy.—The chief remedies which are dangerous to the pregnant woman are salicylate of soda and ergot. Purgatives—castor oil, mineral salts, and especially aloes—should be avoided. Quinine in too large doses must also be omitted; when given at all it should be guarded by combination with opium.—HUGENIN.

Centenarians in France.—A census of centenarians recently taken in France gives 213 persons of one hundred years or over, 147 of them women and 66 men. The oldest was a woman who had just died at one hundred and fifty, in a village of the department of Haute Garonne. Nearly all the centenarians belonged to the lowest ranks in life.

Hospitals for Tuberculosis.—At the recent meeting of the American Climatological Association it was noted that, "Since tuberculosis has been demonstrated to be a communicable disease, it has become doubly desirable that hospitals for the reception of the poor afflicted with the disease should be established," and the Association resolved to "recommend the establishment of such hospitals in every State, not only for the relief of the great suffering attending this disease among the poor, but also as a protection of the community against its spread."

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

EASTBOURNE POSTPONES HER INVITATION—THE ANNUAL EXODUS—DR. SAMBON'S COLLECTION OF MEDICAL ANTIQUITIES—MR. VICTOR HORSLEY'S QUESTION AT THE MEDICAL ASSOCIATION—OFFICIAL ANSWER—SALVATION SHELTERS—SMALL-POX—VACCINATION ACTS.

LONDON, August 24, 1895.

IT seems that the British Medical Association is not to visit Eastbourne next year after all. The reason reported is that the local profession is hardly prepared to support the proposal of the mayor, but will probably be desirous of doing so two or three years hence. This may be a disappointment to some of our northern friends, but Londoners are mostly acquainted with the attractions of Eastbourne. I confess to a little surprise that the local doctors should not have been eager to seize the opportunity of what is, after all, a capital advertisement of their pleasant health-resort. Perhaps they are deterred by the expenses that have been incurred in the London visit, for unfortunately the excursions on this occasion have been costly, no doubt, because the metropolis has plenty of attractions within itself, and provincial visitors did not care to take country trips. Some other town will, no doubt, after a while offer an invitation.

Those of us who are left in town feel a relief that the meeting is over, not but what it has been a great pleasure to have our houses filled with our country friends, but the hospitality involves an amount of fatigue and anxiety to make our guests happy, after which a rest is grateful. The usual exodus has taken place and London is said to be empty, but there are plenty of doctors for all the requirements of the public, although so many are taking their holidays. Every one of the staff of reporters who worked so assiduously for the MEDICAL RECORD at the meeting disappeared immediately afterward, and some of them copied their reports in the country.

Among the most interesting events of the meeting was the exhibition of medical antiquities collected by Dr. Sambon, of Rome, which the members were invited to inspect by Messrs. Oppenheimer, who certainly deserved thanks for so instructive and interesting an exhibition. Dr. Sambon's collection includes a great number of ancient instruments such as probes, directors, tenacula, lancets, clamps, specula of various kinds, and other instruments, most of them in bronze, and artistically ornamented and finished in a manner worthy of a modern instrument maker. Then there were a number of donaria in terra-cotta—such as were presented to the gods and preserved in the temples in commemoration of cures. Everyone with a taste for antiquities must appreciate such a collection.

A good deal of amusement has been excited by Mr. Victor Horsley's attempt to obtain from the Council a simple answer, yes or no, to the question: whether that body or, as some say, "the ruling clique," will carry out the directions of the general meetings? The official answer given him was "that the Council had always acted on the principle that resolutions of the annual meeting were an instruction to carry out the policy indicated, unless in contravention of the memorandum of association." I am surprised that any gentleman should undertake to make such an assertion, considering the many times such resolutions have been treated with contempt; for example, when the Brighton meeting expressed a determination to take no part in the election of a representative on the General Medical Council, the clique adjourned to an hotel and resolved to support one of themselves as a candidate, and used

all the power of the Association to carry their determination. Again, notwithstanding the condemnation of the Notification Acts at the Worcester meeting, they have ever since been supported by the *Journal*. We shall see whether the *Journal* will now cease to push the registration of midwives, now that the last meeting has distinctly condemned that policy. It is unfortunately too true that the Association is no more than a limited liability company for publishing a cheap journal, and that at enormous cost, to the great advantage no doubt of its well-paid editor, whose travels in various lands may stimulate the formation of new branches, but can scarcely be remunerative to the Association or promote the interests of the British members. Great hopes were entertained that when ten thousand members had been attained, reforms would be supported and legislators would listen. Now that so much larger proportions have been attained the profession still speaks in vain. Can it be that an ex-minister was right when some years ago he remarked, "that if doctors wished their wishes attended to they should choose a different representative to express them?"

The medical officer of health for St. George's, Southwark, has summoned the officer in charge of the Blackfriars Shelter of the Salvation Army, for creating a nuisance injurious to the public health. This is the shelter which proved the focus for small-pox, and now it appears that on inspection more than double the number of persons were admitted than ought to occupy the space at command. It is high time the Salvation Army and other so-called philanthropic bodies should be called to account for their neglect of sanitation and the danger they ignore of disseminating infectious diseases. Why should not a man who communicates disease to his neighbor be held liable in damages? Employers have to pay their workmen for accidents which might have been prevented, and a disease is often worse than an accident. Small-pox continues to spread in the East End. This is the result of the neglect of vaccination, which has been deliberately evaded with the connivance of boards of guardians. It is suggested that the administration of the Acts should no longer be entrusted to these Boards, but to a central authority, say—the Local Government Board.

RELIGION, DISTURBED INDUSTRY, AND SUICIDE.

To the Editor of the Medical Record.

Sir: In the admirable compilation on "Suicide in the United States," which appeared in the Medical Record of August 17th, I think Dr. Weir has overlooked two prime factors controlling the proportion of suicides among different peoples, and at different places, namely, religion and disturbed industrial conditions. The first factor is negative or prohibitive in operation. It receives not the remotest reference in the article named. The second might be inferred, by the student of economics, from the author's reference to "condensation of population," which, of course, involves keener struggle for existence leading to the despair of the weaker and unfortunate. That the latter is a force paramount in the production of the increased suicide-rate of recent years, is abundantly demonstrated by the author's own figures and, taken in connection with the influence of the Church of Rome and churches of similar tenets regarding suicide, sufficiently explains certain variations of the suicide-rate without the necessity of any abstruse theory of inherent national psychoses, or at least gives a tangible foundation for a working theory.

First, taking into account the prohibitive character of the Roman Catholic teachings, we find that they explain the comparatively smaller proportion of suicides among the Celts and Celto-Latin peoples, as compared with the Germanic peoples, and the Slavic peoples, as compared with the Germanic peoples, and the Celto-Latin peoples, as compared with the Slavic peoples. Thus, the Celts and Celto-Latins, with the exception of the Celts of Ireland, are the most joyous and pleasure-loving of the European peoples, and the Celts of Ireland are the most joyous and pleasure-loving of the English-speaking peoples. Their religion is the most joyous and pleasure-loving of the Christian religions. Their religion is the most joyous and pleasure-loving of the Christian religions. Their religion is the most joyous and pleasure-loving of the Christian religions

tion from the pressure of absolute want. It was a period of suspension of industry, strikes, lockouts, and labor insurrections, when the condition of the mass of the people was productive of the causes of suicide. I have examined a *résumé* of incentives to suicide, as shown by the coroner's inquests in Cook County for this period, and it shows a progressive increase among suicides due to poverty and want.

Dr. Weir's figures regarding the suicide-rate per million in the State of Massachusetts curiously bear me out here. Massachusetts is a manufacturing State, and during the prosperous years 1889, 1890, and 1891, when its factories were in full blast under the protective tariff stimulus, the rate sank from 91 to 81 per million. With 1892 came the suspension of factory work in Massachusetts, and with this suspension want and suffering among the people, and a consequent suicide-rate of 115, which under a continuance of industrial paralysis rose in 1893 to 119. What I hold is, that in view of disturbed industrial conditions, Dr. Weir's conclusions that an absolute and continuous increase in the suicide-rate is to be expected, are insufficiently borne out by the facts. They prove nothing more than that, with conditions favoring the development of want and misery among the people and thus fostering the incentives to suicide, proportionately more people, acting under the increased pressure, will succumb to the temptation of self-destruction. The conclusions regarding the world's suicide-rate in general are open to the same criticism, because his comparisons are all drawn between past years of comparative prosperity and the rate for the year 1893, when industrial stagnation and distress were general; the period of financial, labor, and trade upheavals when, I repeat, the incentives to suicide were vastly greater than at most any other period of recent history.

Respectfully,

C. L. Bennett, M.D.,

Surgeon to La Gran Fundicion Central Mexicana.

Aguas Calientes, Mexico, August 26, 1895.

THE ETHICS OF CRANIOTOMY.

To the Editor of the Medical Record.

Sir: It is possible that you are becoming wearied with the subject, but the last letter by Dr. Kearney has placed the discussion of craniotomy on a broader basis than it had heretofore had. The conclusion, however, is so very lame and unsatisfactory, that I cannot forbear asking leave to present one view of the question that has not yet been mentioned. I suppose Dr. Galloway well able to fight his own battles, and I wish to refer only to the last paragraph of Dr. Kearney's article in the Medical Record of August 31, 1895:

"Thus I affirm, it is plainly seen that there is no system of moral science whose teachings can be appealed to in support of Dr. Galloway's contentions. There is nothing, then, for him to do but either to accept the behests of the moral law as we now understand them or to found a new school. To do this latter, however, he must discover some principle or principles of ethics that have hitherto eluded the profound thinkers of the past, for most surely the principles he advances, if pushed to their legitimate logical consequences, will lead to moral chaos."

Procuring the death of the fœtus to save the life of the mother is, I am sure, to be defended on ethical grounds. The principles of ethics applicable to the case have already been enunciated and are now generally received by thinking men. The only difficulty is that these principles have not been yet distinctly enough applied to the case in hand.

We may safely assume, I believe, that the theory of evolution is the best working hypothesis in every branch of natural science. We are learning, through Herbert Spencer and all late writers on ethics and politics, that the same principle will best explain the facts. History is being rewritten from an evolutionary standpoint. Under the teaching of the school of Lombroso, even the criminal code is changing to harmonize with the same great principle.

The theory of gradual development, Darwinism, for a popular name, has proved to be the most far-reaching, stimulating, and helpful principle ever enunciated. Now that we have had the last word on the subject of craniotomy from the church, and from precedent in jurisprudence with their conflicting decisions, and a reduction to a "moral chaos," why not ask what the principle of development, which has helped us out of so many quagmires, will do for us.

Let us admit two propositions—that man has developed from the lower forms of animal life, and that the development of the individual corresponds to the development of the race up to that point. If these principles are denied, I have not the space or ability to go through the voluminous proof that seems to me convincing.

If these are admitted, it seems to me it must necessarily follow that, while the human embryo is from the first alive, it is not a human being until it has developed and differentiated to such a point as corresponds to that point at the birth of the race where the animal became a man. I am sure I do not know just when that occurred in the past, and I do not know at what point it takes place in the individual. I am sure, however, it is a good ways this side the act of copulation, that it is this side the fourth week when it is impossible to distinguish the human fœtus from that of a cat. In inquiring for that distinctive feature which distinguishes the man from the animal, I find none but mentality. If we wait for distinctive mentality to appear in the development of the individual, it would be some time after birth.

I am well aware that the idea arouses antagonism and inflammatory denunciation in some minds. That it will prove to be the true one, however, depends only on the truth of the general theory of development. That it is already held by some is shown by this sentence from a recent article by Lombroso (*The Forum*, September, 1895, p. 42). The original referred to I have not yet been able to obtain. "Balestrini made a wonderful study of infanticide and abortion, and demonstrated that in the case of abortion, especially, what is killed is not a man, but a being inferior in the zoölogical world."

F. W. Higgins, M.D.

Cortland, N. Y.

Silly Old Folks.—One of the daily papers recently published an account of a boat-race rowed at Deal, England, between four four-oared crews of boatmen over sixty years of age. The winning oarsmen averaged seventy years, while their coxswain was eighty-five. At the same time appeared an item concerning two women in Maine, one sixty-nine and the other eighty years of age, who held the championship of their town for rope-skipping. It is a pity these hale old people have not as much wisdom as they have physical strength, to prevent them from abusing the latter.

The Term "Uricacidemia" recently was stigmatized in these columns as a fearful mongrel never employed by educated writers. This assertion, however, is not altogether true, it seems. For in a late number of the *British Medical Journal* the eminent Dr. Haig employs, unreservedly, this wonderful combination of two English words and a Greek suffix. Hereafter no one will be surprised to see crop up in medical literature such vocabulary beauties as whitebloodcorpuscleemia, grapesugaruria, eggwhiteuria, gallstoniasis, stomachguttitis, etc. Verily, the English language has lost nothing of the flexibility and adaptability of vigorous youth.—*Western Druggist.*

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending September 7, 1895.

	Cases.	Deaths
Tuberculosis	95	98
Typhoid fever	31	8
Scarlet fever	21	4
Cerebro-spinal meningitis	2	5
Measles	68	3
Diphtheria	137	26

The Ear in the Exanthemata.—Among the preventable diseases, which have so often been allowed to gain ground through neglect at their first onset, may be counted otitis media suppurativa following the exanthemata. The aural surgeon meets such cases every day, and more often than not they have been neglected by parents because they believed in the absurd and ignorant fallacy, that the patient "would grow out of it." Now, thanks to the improvement in the education of the general public, we may hope that these cases will become less in number, and that some of the more alarming complications of exanthematous otitis media may be met with less often. Quoting recent statistics, it may be said that out of 501 cases of middle-ear disease in children, 131 originated during an attack of measles, 63 during scarlet fever, 147 owed their origin to catarrh, and 101 to teething; so that it will be seen that some two fifths arise in measles and scarlet fever. Now, without going deeply into symptomatology, it is only necessary to point out how these diseases give rise to pharyngeal troubles, causing blocking of the Eustachian tubes, and the accumulation of secretion in the tympanum. Since the Eustachian tubes drain better in the upright than the recumbent position, the child suffering from measles or scarlet fever is placed at a further disadvantage, as pointed out by Walker Downie, who consequently insists upon the frequent and strong use of the pocket-handkerchief to keep the nose and naso pharynx free from the very beginning of the illness, when there are catarrhal symptoms. If the child is too young, politzerization can always take the place of the handkerchief. The pent-up secretion in the tympanum gives rise to considerable pain, and if this be not relieved by the means just mentioned, the risks of future otorrhœa can be best avoided by paracentesis of the membrana tympani. If done at the lower and posterior part of the membrane, with a shouldered myringotome under proper focal illumination, the child's head being securely held, this little operation is perfectly safe and simple, and the wound readily heals. If the patient be the subject of adenoids, these must be left until recovery from the exanthem. It cannot be too deeply and strongly impressed upon the public that it is during the primary febrile disease that the ear requires care, and that a discharge from that organ during measles, scarlet fever, or small-pox, means culpable neglect and carelessness. Inquiries as to the ear should be made at every visit, and an occasional examination with a speculum insisted upon. Further, when earache is complained of, it is by the simple and scientific methods mentioned above that relief must be afforded, and the ear (perhaps also the life) saved, and not by the palliative means of blisters or leeches.—*The Medical Times.*

The Royal College of Physicians.—In the tenth year of the reign of Henry VIII., on September 23, 1518, "John Chambre, Thomas Linacre, Ferdinand de Victoria, Medicorum Nostrorum, Nicholas Holsack, John Francis, Robert Yaxley" were granted letters patent giving them the privilege of admitting men to practise medicine in London and seven miles around. This was the original foundation of the present Royal College of Physicians of London. The first letters patent having apparently been inadequate for the purposes intended, in the fourteenth year of Henry VIII. a statute was passed enacting that no person save a graduate of Oxford or Cambridge should practise in England, unless he had a license from the President of the College of Physicians aforesaid, and from three of the "Elects," who were chosen from among the Fellows.

Medical Students in Italy.—There were 19,048 medical students registered in Italy in 1894–95. The number of universities is twenty-one, and the number of students registered at the various universities varies from 3,697 at Naples to 87 at Milan. The percentage of medical students to the population is about 61 per 100,000 inhabitants. In France it is 57 per 100,000, and in Germany 63 per 100,000. In Italy, university education is chiefly supported by the State, the students paying only a yearly tax of 200 or 300 francs. According to the latest statistics, after subtracting the tax paid by the students, each student costs annually to the State a sum which varies from a minimum of 215 francs at the University of Naples to a maximum of 1,408 francs at the University of Siena. It appears from the returns that the larger the number of students at a university, the smaller the annual expenses for their education.

Acne Rosacea.—Freeze the part with a rhigolene spray or ethyl chloride, and freely scarify with a five-bladed knife. This treatment gives prompt relief.—CANTRELL.

NEW BOOKS RECEIVED.

While the MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will be promptly made of their receipt under this heading, it must be with the distinct understanding that its necessities are such that it cannot be considered under obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

EXERCISE AND FOOD FOR PULMONARY INVALIDS. By Dr. Charles Denison. 12mo, 71 pages. Illustrated. Price 35 cents. Published by The Chain & Hardy Co., Denver, Col.

THE DISEASES OF THE LIVER: JAUNDICE GALL-STONES, ENLARGEMENT, TUMORS, AND CANCER: AND THEIR TREATMENT. By J. Compton Burnett, M.D. 12mo, 244 pages. Illustrated. Price, $1.00. Published by Boericke & Taffel, Philadelphia.

INDURATIVE MEDIASTINO-PERICARDITIS. By Thomas Harris, M.D. 8vo, 67 pages. Illustrated. Published by Smith, Elder & Co., London.

TRANSACTIONS OF THE MEDICAL SOCIETY OF THE STATE OF PENNSYLVANIA, HELD AT CHAMBERSBURG. FORTY-FIFTH ANNUAL SESSION, 1895. Vol. 26. 8vo, 504 pages. Published by the Society. The Edwards and Docker Co., Philadelphia, Pa., Printers.

PRACTICAL DIETETICS. WITH SPECIAL REFERENCE TO DIET IN DISEASE. By W. Gilman Thompson, M.D. 8vo, 801 pages. Illustrated. Published by D. Appleton & Co., New York City.

THE THEORY AND PRACTICE OF COUNTER IRRITATION. By H. Cameron Gillies, M.D. 8vo, 236 pages. Price, 6d. Publishers, Macmillan & Co., New York City.

PREVENTION OF UTERINE DISEASE DUE TO CHILD-BEARING.[1]

By W. GILL WYLIE, M.D.,

NEW YORK CITY.

Most of my work as a physician and surgeon has been devoted to effecting cures of diseases as we find them in women after child-bearing, but the first ten years of my practice was that of a general practitioner, and I still take a limited but sufficient number of selected cases of obstetrics, to make the matter one of great interest and more or less of a study. During the past fifteen years, which I have devoted mainly to the development and improvement of the art of gynecological surgery, there has been a great advance in this work, so much so that in our annual meetings papers on any other subject than surgical gynecology are rare. Besides, it seems to me that we have reached the point where we should at least attempt to divert some of the immense interest and almost general devotion manifested not only by men especially trained in gynecology, but by the profession at large, to what may well be termed fashionable surgical gynecology, to that higher plane of our work as physicians, namely, to the prevention of disease. To-day, as physicians and artists in surgery, we can readily relieve, and in almost all cases cure, the special diseases of women promptly and accurately with very little risk to life, and we can well afford to turn our attention and direct our efforts to the prevention of such diseases. Fifteen years ago many important diseases of women were improperly treated, and the practice of the art of gynecological surgery was of very doubtful practical value to our patients; but to-day there are hundreds of accomplished artists in our ranks who can and do effect cures of these diseases, and there are many thousands more of the profession who, if they keep up the interest and their readiness to operate, should become expert or kill many women. How much better it would be if we could succeed in getting up an almost universal interest, and one might say fashion, in our profession to prevent many, yes, most, of these cases? How much greater and more real our help toward the health and happiness of womankind would be?

Suppose one had the power to direct the immense amount of energy, interest, and work now so intensely and enthusiastically devoted by not only all specialists in gynecology, but one might say nearly all of the profession who think themselves capable and are so willing and anxious to sew up lacerations, remove ovaries, and do hysterectomies, etc., to the prevention of diseases of women, what an amount of good to mankind and especially to women would result? The work might not be so exciting, nor so brilliant, nor immediate in tangible results, but much greater in the highest sense of the word. We will endeavor to enumerate some of the plain and practical fields of work in which much of this great force might be made really useful.

As physicians we can do much by urging on parents to keep girls in good health, especially during the time that the generative organs are undergoing rapid development, say from ten to seventeen years of age. The generative organs are not essential to the life of the individual and are the last of the organs to develop; therefore they are the first to suffer if the forces essential to full development are used up too closely by excessive work, deficient food, or want of fresh air and exercise, especially if the work or the life uses up or expends this force in mental or emotional excesses. In fact, it seems absolutely essential to the full development of the generative organs of a woman for her to have a surplus of force over and above what is needed for the uses and development of the other organs of the woman.

Imperfect development of the generative organs results usually in a small flexed uterus, with catarrhal erosions and chronic endometritis, causing leucorrhœa, dysmenorrhœa, and, later, in sterility or lacerations of the cervix, subinvolutions, displacements, etc.

It is the duty of physicians to impress upon newly married women the necessity of keeping in good general health during pregnancy. By keeping the bowels regular and taking some special food such as would be easily digested, and other means to keep the general health good, both the mother and child can be made to reach the full term in good physical condition.

By actual experience I have proved that by careful feeding and attention to the general health during pregnancy, and induction of premature labor when indicated, it is practical to avoid craniotomy or Cæsarean operation in most cases of deformity, and even where the uterus is imperfectly developed, or the os eroded by disease of the follicles and glands of the mucous membrane, by inducing labor from one to three weeks before full term we can not only avoid difficult labor and laceration of the imperfectly developed or diseased cervix uteri, but the forceps become, except in rare instances, unnecessary. If the pelvis is below the average size, or if there is any deformity; if the husband's head is excessively large and the woman small; or if there is imperfect development or chronic disease of the cervix, I do not hesitate to induce labor before full term, especially in primipara. If the first labor is after the woman is thirty years old or more, it is best to induce labor a week or ten days before full term. About the end of the seventh month or before the end of the eighth month I invariably examine, to determine the condition of the parts and the position of the head. As a rule one can easily perform external version if he finds the head not presenting in a normal position.

I do not advise induction of labor without a good reason, but I know that it can be done by an expert who understands and practices cleanliness and the use of antiseptics with practically no more danger to either child or mother than labor at full term. Not only is the labor when properly induced shorter and easier on account of the relatively smaller child and softer and therefore more malleable head, but as the time of labor is positively known, everything is in readiness, and both the nurse and doctor are present without fail, and cleanliness is carried out with more accuracy, and accidents from hemorrhage, etc., more certainly avoided. The method of inducing labor which I have found to be practically the best in my hands is an old one. Observing all rules of cleanliness, I use the tincture of

[1] Read at Baltimore, May 29, 1895, before the American Gynecological Society.

green soap to wash not only the patient, but the hands of nurse and doctor, supplemented by a solution of hydrarg. bichloride 1 to 3,000. If the vagina is small, or if the induction is more than a week before full term, I move the patient's bowels well, and by the use of a clean and new rubber colporteur I distend and soften the vagina for several hours or a day before inducing labor. I then take an old-fashioned gum catheter, a new one, wash and disinfect it, partly fill it with iodoform, and start the introduction with a properly curved stylet so as to be able to pass the catheter up anteriorly to the presenting head. After giving it a fair start the stylet is withdrawn and the catheter carefully passed up till it is all well up in the uterus, lying between the membranes and the anterior wall of the uterus, with from one to three inches of the lower end in the vagina. The catheter is introduced at bedtime, and usually two ounces of castor-oil is given by mouth. One must, if possible, avoid rupturing the membranes when introducing the catheter. With rare exception labor pains will begin the next morning, and when labor is fairly started the catheter is withdrawn. I have tried the glycerine injections and other methods, but prefer the one given above. Glycerine injected in the pregnant uterus, when it remains will induce labor, but it often causes alarming pain in the head and intense oppressive sensations about the chest; besides, the labor is induced too rapidly and the tissue may not have had time to soften and properly dilate.

Prevention of sepsis after labor or abortions is now so well understood that it is only necessary to urge the simple but efficient means used in almost all of our lying-in hospitals and used in private practice by many of the profession. In 1870, twenty-five years ago, when I began practice as an intern in Bellevue Hospital, the death-rate in the lying-in wards from puerperal fever was every year from five to twenty-five per cent. of all women delivered. To-day many hundreds of consecutive cases are delivered in our best lying-in hospitals without a death from sepsis. In the spring of 1872, when it was my turn to take charge of the lying-in wards then in Bellevue Hospital, I had become a convert to the germ theory of disease and had been fully imbued with a faith in antiseptics by my old preceptor, the late Dr. James R. Wood. By throwing away all sponges and old oil-cloths, and personally attending each case in all its details of cleanliness, and treating each case with all the care that I would bestow upon a wound, I delivered all of my forty-one cases without a death from sepsis. In July, 1872, I had the advantage of seeing the great Lister at work in Edinburgh, and brought home with me to New York his methods and appliances for treating and dressing wounds, making practical application of his teaching from that day to this on all women that I have ever attended, after either a labor or abortion. So far I have never yet had a death from any cause, after either labor or abortion, which I have attended, and only one had sepsis which endangered the life of the patient. To day I find that there are many of my colleagues in the profession under forty-five who have had for many consecutive years the same good fortune.[1] Thirteen years ago, in a paper read before the New York County Medical Society and published in the MEDICAL RECORD, I gave an account of my method of preventing and treating sepsis after labor and abortions. To-day I use the same methods somewhat simplified. I will now briefly relate the means I now carry out in every case.

Prevention of Sepsis after Labor or Abortion.—Before agreeing to take a case it must be stipulated that I am to have full charge of the case in every sense of the word The nurse must be one of my own training, or at least selected by me. Before labor is expected the nurse must be in the house with all medicines, instruments, etc., likely to be needed, on hand. The room to be used is cleared of all stuffy furniture and hangings and given a thorough cleaning; a sheet or two is tacked over the carpet where the new cheap and strong cot which is to be used to deliver on is placed; all towels, bedclothing and linen is to be especially laundered, so as to be practically sterilized, and kept in readiness. On or before the first indications of labor beginning the patient is given a complete bath if there is time, or, at any rate, the vulva and vagina are well scrubbed and washed with tincture of green in place of ordinary soap, and the parts washed off with 1 to 3,000 solution of hydrarg. bichloride. The nurse must have on a clean wash dress, and I put on a surgical gown; my hands and the nurse's are always washed with tincture of green soap and dipped in a solution of bichloride each time before examining the patient. During and after labor a solution of bichloride, 1 to 3,000 or 4,000, is used to wash off the vulva. If there is time the bowels are well moved by castor-oil, and always the rectum emptied by enemata; all instruments used have been sterilized by boiling, and put in a solution of 1 to 40 carbolic acid before being used. Any hemorrhage is checked by emptying the uterus of placenta or clots, and, if necessary, by ligation of the circular artery when the cervix is torn or by sewing up the perineum when torn. Any tearing of consequence to the perineum is sewed up. After labor, except in cases complicated by severe hemorrhage or lacerations requiring sewing, the patient is made to sit up to pass water or have the bowels move. For a full week the antiseptic napkins or absorbent pads are kept over the vulva and changed every few hours as required by the discharge, and after each time the bowels move or the patient passes water the vulva is washed off by means of a David syringe and solution of 1 to 3,000 of bichloride of mercury. This is kept up faithfully for seven days after labor. On the sixth or seventh day the patient sits up out of bed. On the tenth day the patient is carefully examined as to the condition of the parts, the character of discharge, and position and condition of the uterus, and to decide if any local treatment is needed to insure normal involution and prevention of subinvolution of the uterus, relaxation of the ligaments, and displacements of the uterus. No vaginal douches are given after labor unless instruments have been used to deliver, or hands have been introduced into the uterus, or there is a rise of temperature or an odor to the discharge.

I will not discuss the questions as to the methods of delivering the child in abnormal labor, for the art of delivering the child and membranes is well understood and better taught by those who have devoted more time to, and have had much more experience in, the art of obstetrics.

Treatment of Acute Sepsis Occurring after Labor and Abortions to Prevent its Extension or from Causing Permanent Injury.—In the paper already referred to I gave fully my views and methods on the local treatment of sepsis after labor and abortions, and would be content here merely to state the method, but I am satisfied that what may be called the fashionable methods now being resorted to and so ably advocated by some of my colleagues has a very radical defect when applied to any but fresh and rather superficial septic uterine infection. I mean curettage and gauze packing, as it is called. Of course in all cases where it is possible the uterus should be emptied, but there is an erroneous belief and teaching now very prevalent, namely, that sepsis is caused by retained placenta, and all that is needed to cure is to curette it out and pack the uterus with iodoform gauze. It is true that retained placental tissue and clots make a very favorable nidus and food for septic germs, and undoubtedly make sepsis more liable to increase when it is present, and lessen the chance of the normal tissues defending themselves, and

[1] I must confess that all of my cases, except in the very first few years of my practice, were among the best class of well-to-do women, able to pay for the best nursing and to compensate me for the closest attention.

thus make sepsis more dangerous, but uninfected placental tissue will not cause sepsis. Of course it should be removed, and it is very important to remove or give free drainage to all effete tissue, when once the septic germs become active, if we are to treat the case successfully; but sepsis will, as we well know, start up and kill when there is no such thing as a placenta about. My belief is that septic germs must have some effete material, or at least defective organic matter, to develop and thrive in and cause the kind of sepsis which first infects a puerperal woman; but the presence alone of such material will not cause sepsis.

Now, as to the use of gauze as a drain in ordinary cavities where the secretions or excretions are thin and watery. Loosely packed gauze drains well, but the uterus in the condition is different. It has in it many glands and follicles which secrete or excrete, especially when irritated or inflamed, a thick gummy material, which after a few hours soon chokes drainage through gauze, and what escapes passes around and in spite of, and not through, the gauze. Besides the uterus is a contractile organ with a very powerful sphincter guarding its mouth, and as soon as contractions begin this constricts the gauze and obstructs drainage. I admit that in all cases the uterus should be carefully emptied, but I prefer the combined method of the hand or fingers and forceps where this is practicable. After removing with forceps all large pieces, I very carefully run a large-sized curette over the surface to bring away small adherent pieces; but soon after labor and abortions, especially when rendered soft and patulous from sepsis, it is an easy matter to push a smallish curette entirely through the uterus, and it is not an infrequent occurrence. Again I admit that soon after the first chill and rise of temperature from puerperal sepsis in most cases, if one empties well the uterus of all clots and retained placenta, and all material favorable to the rapid development of sepsis, that one good antiseptic washing out and loose packing with gauze will check the sepsis, and in many cases effect a cure; but, where there is failure to effect a complete emptying of all, or almost all, of the effete material, or at least that part of it already infected by sepsis, curetting and the preceding method of gauze-packing will not effect a cure even when supplemented by one washing out, and when it fails and the gauze is left in over twelve or twenty-four hours it increases the danger to life by tending to keep the septic material in the uterus, and where there is a close packing with gauze it tends to force the sepsis into the sinuses, veins, or Fallopian tubes; that, in cases of sepsis which have existed for several days, the curettage and gauze-packing is much more likely to fail to effect a cure, for the sepsis has had time to penetrate deeper into the uterine tissues. Of course when the septic material has entered the peritoneum or is located in the veins or lymphatics outside of the uterus no local treatment of the uterus can effect a complete cure. We will assume that the septic material, the centre and source of the infected matter, is still within the uterus and has not yet infested the peritoneum nor the lymphatics and veins outside of the uterus. For experience teaches us that for many hours, and often two, three, and four days or more, in most cases the septic centre which causes the symptoms is still confined to the uterus. In all cases, unless we can clearly detect local sepsis within the peritoneum, the lymphatics, veins, or some tissue outside of the uterus, we must at once act on the assumption that it is still confined to the uterus until we have tested the matter by actual emptying and local treatment of the uterine cavity. Now, I believe that the method which I proposed, practised fifteen years ago, has proved by experience and direct comparison to be more reliable than the method now known as that by curettage and gauze-packing. Being called to see a case of puerperal fever, it will not do to examine, and finding a laceration of the perineum or cervix, to assume that a small, open wound, except in rare forms of septic poison, such as true diphtheria, can cause the symptoms of a severe or dangerous puerperal sepsis. After washing out the vagina and cleaning off and cauterizing with pure carbolic acid any torn or lacerated tissue a few times, unless there is rapid and continued improvement I soon begin by washing out the uterus, which will as a rule be found patulous and readily dilatable in septic cases, with a solution of 1 to 40 of Calvert's No. 1 carbolic-acid solution. Beginning cautiously and carefully, I give the whole cavity a soaking wash of two quarts or more, then with my hand, fingers, and forceps where it is practicable, I empty the uterus of all clots and effete material. If it is an old case, I first dilate the os well with steel dilators, but never with tents of any kind, and after running a large-sized curette over the surface to get off all small adherent tissues I swab out well the whole cavity with pure carbolic acid rendered soluble with a little glycerine and water and immediately follow this up by washing out the uterus with a hot solution of carbolic acid, 1 to 60, injecting a quart or more. If the uterus is large and very patulous I may use a large-sized Chamberlain's glass tube, but in all other cases, and after the first washing or two, I invariably use a large-sized No. 12 or 14 old style stiff-gum catheter. I introduce the catheter well up to the fundus, with a stylet in it. Then I fill the catheter with water after removing the stylet, and connect it with an ordinary Davidson's syringe. Beginning my injection very slowly and gradually turning the catheter about in the uterus, I pump the water with full force as soon as it begins to run out of the vagina freely. I aim to completely flood the whole cavity and use not less than from one to two quarts of 1 to 60 solution of Calvert's No. 1 carbolic acid. Immediately after the first washing out in acute or severe cases the patient will have as a rule a chill and rapid rise of temperature, which is undoubtedly due to increased abortion from the fresh wounds to the mucous membranes by the instruments used.[1]

The reason I use the catheter is that it can be readily adapted to any size or position of the uterus, which often hardens up and flexes sharply as soon as the sepsis is checked, though poison may not yet be completely eliminated and is liable to develop again and renew itself in full force. Glass tubes often fail to reach the fundus after a few washings. Double recurrent and other theoretical contrivances often fail to do more than wash out a small section of the cavity by running in at one eye and out at the other, and those fine contrivances which aim to forcibly distend the uterus or vagina before emptying the fluid are very liable to force the septic material through the Fallopian tubes into the peritoneum. It takes an expert to reach the fundus and wash out efficiently as the uterus begins to contract, for failure to wash out or kill all germs means a relapse.

To empty the uterus and wash it out is very important, but unless the first washing is followed up by another washing in about one hour after the first is finished, especially if an interval of three or more hours is allowed to intervene, the treatment will utterly fail in many cases; in fact, in almost all except in very fresh and simple cases of septic infection. In from three to eight hours the germs left have found effete material to develop on, excretions and mucus cover the surface, and almost all of the original local sepsis has been reproduced. Thus it is essential to wash every hour, until the escaping fluid is practically clear of all, especially all dark-colored, material and the temperature has fallen to or nearly normal. As the water returns clearer and clearer the temperature sinks gradually, and, as a rule, after five or six washings the temperature is near the normal mark and will remain so. If the temperature does not materially fall after five or six washings, then the fever is kept up by other sources of sep-

[1] This rapid rise of temperature has caused many a beginner to give up washing out the uterus, prejudicing him against the method.

tic infection, and we must find them and when practical must operate to get rid of the sepsis.

I have tried different antiseptic solutions in washing out the uterus and prefer 1 to 60 to 1 to 100 solution of Calvert's No. 1 carbolic acid. It is safe, does not constringe the parts, and soaks into the tissues and softens them. It is possible that the carbolic acid enters the circulation and acts favorably, but it is its local action that I rely upon. If more than six hourly washings are required to control the sepsis I use alternately a solution of boracic acid. If one will watch the urine there is no danger of carbolic-acid poisoning, for the urine becomes smoky and plainly indicates that the carbolic-acid injections should be stopped or at least lessened. In old indolent sloughing cases I use peroxide of hydrogen or iodoform, and usually insert a large hard-rubber inter-uterine drainage-tube. Bichloride of mercury cannot be used safely except in weak solution, 1 to 5,000, and not too often; besides, it constringes the tissues and interferes with free drainage and insertion of the tube.

A Simple Method to Insure Normal Involution After Labor or Abortion, and Prevent Chronic Endometritis, Relaxation of Ligaments, and Displacements.—Many years ago I discovered if boro-glyceride (not glycerite or a simple mixture of boracic acid and glycerine) was combined with pure glycerine in solution ten to twenty per cent., that we could saturate cotton pledgets with it and apply in the vagina with the best possible results, that there would be no ferment of the glycerine and secretion to cause irritation, etc., and that it would excite an immense amount of secretion from the uterine and vaginal glands when left in for twenty-four hours. I advocate the use of these pledgets twice or three times a week in the vagina in all cases where I wish to improve the pelvic circulation and thus reduce the size of the uterus and relieve the over-congested tissues in all parts of the pelvis. I have had especially good results in all cases of subinvolution after curetting and draining the uterine cavity; that it was much more rapid and certain than the prevailing plan then in use and now so much practised, of rest in bed, hot vaginal douches, etc. Besides, by making the roll of absorbent cotton firm and 1¾ to 2½ inches long and from 1 to 1¼ in diameter, that a sagging and retroverted uterus could be readily held up in a more natural and better manner than by a hard pessary. The active circulation caused by the boro-glyceride and glycerine mixture contracted the vaginal tissues so that the cotton pledgets remained in place, and this contracted and firm condition of the tissues would continue for a day or so in most cases, thus enabling the patient to go about without trouble for twenty-four to forty-eight hours after removal of the cotton and give time to cleanse away the coagulated mucus, etc., from the vagina.

For full fifteen years I have practised and taught the use of this simple treatment in all cases after abortions, especially when there was any kind of inflammation or hardening of the uterus complicating the abortion, and in all cases after labor where one desires to insure a return of the uterus to its normal size and position in the pelvis. In many cases among the well-to-do class, in our cities at least, there is a marked tendency for women to have more or less trouble after labor. The general health is not good or the uterus is not well developed, and the cervix is torn, and on account of the relaxed and bad general health or disease of the cervix, it fails to heal and subinvolution, chronic endometritis, and displacements follow.

Many years ago I also discovered that many cases of melancholia and extreme nervousness and sterility are due to chronic subinvolution or enlargement of the uterus, and that when we cured the subinvolution or the local disease or condition the melancholia in many cases would disappear as if by magic. Some of these cases were classed as insane and were considered incurable, but were entirely relieved of all actual symptoms by reducing the uterus to its normal size and curing of any existing local disease. I do not mean to say that melancholia or tendency to disturbed mental balance is eradicated, but that enlargement of the uterus and associated local disease will in some women, not all, cause or excite melancholia, and that a cure of the local disease will cure the abnormal mental disturbance called melancholia. This experience led me to use the boro-glyceride cotton pledgets to prevent subinvolution, especially in very nervous women who had had melancholia or other forms of mental disturbance before pregnancy. About the tenth day after labor I examine the women locally. If the uterus is large and crowded down in the pelvis, or if the secretions are still bloody or abnormal, or if I have any good reasons from previous knowledge of the case to believe that relaxation, subinvolution, displacements, etc., are liable to follow, I put the patient in Sim's position on her left side, push the uterus well up out of the pelvis, and apply a suitable sized and soft, but firm enough to keep in shape, boro-glyceride cotton pledget in the vagina. It is so placed under the cervix uteri, so that the uterus cannot sink down in the pelvis nor fall backward. This is left in place twenty-four hours, then removed by the linen string tied to the proximal end. A vaginal douche of solution boracic acid is given. Two days later the same treatment is applied and repeated twice a week till the uterus is normal in size and position, which usually takes six weeks. At the end of two months after labor if there is any laceration of the cervix complicated by follicular disease the diseased tissue is cut away and the cervix sewed up or amputated and the canal of the cervix is always left lined with a healthy mucous membrane. When amputation is done, the flaps to line the canal are made from the anterior and posterior parts of the cervix. If the perineum is torn, especially the inner portion that supports the lower end of the rectum, it is sewed up also.

By the simple application of the boro-glyceride the patient is able to get out at the end of two weeks without injury and dismissed perfectly cured at the end of six or eight weeks.

For many years past I have followed up some of my old cases of retroversion and flexion where I had sewed up or amputated the diseased tissue of the cervix and restored the perineum, still the uterus would prolapse and retrovert unless artificially supported. When such a case can be got sufficiently well to become pregnant, it is necessary in most cases to keep the uterus from retroverting and flexing till after the third month so as to prevent abortion. This can safely be done by the regular application of the boro-glyceride cotton twice a week or a properly fitted Smith hard-rubber pessary.

After labor, the regular use twice a week of the boro-glyceride cotton pledgets, in such a case, for six weeks will, as a rule, result in a complete cure of all the local trouble.

Smoking.—The use of tobacco does not decline, despite the warnings of hygienists and moralists. According to a tobacco trade journal, there is a steady increase in the number of cigars and cigarettes smoked in this country, and notably in the consumption of cigarettes. During the fiscal year just closed there were sold in the United States 3,333,845,560 cigarettes, and 4,130,440,370 cigars. The increase in the consumption of cigars over the previous year was 68,522,938.

An Attack on the Parasitic Theory of Malaria.—Dr. Lawrie, of Hyderabad, says that there are no parasites in the blood in malaria, and that Laveran and the Italian investigators have mistaken the nuclei of the white cells in the blood for plasmodia.

A CASE OF DOUBLE FORMATION OF THE FACE WITH CRANIO-RHACHI-SCHISIS INVOLVING THE WHOLE VERTEBRAL COLUMN.

By B. ONUF (ONUFROWICZ), M.D.,

BROOKLYN, N. Y.

In giving the history of the above case I must confine myself to a report of the important and interesting points still remaining in memory, as I had the misfortune to lose the notes which I took concerning it.

Mrs. X——, the mother of the hemicephalus in question, had previously borne well-developed twins which reached about the age of two years (?) and died, both on the same day, from an intestinal disease. Mrs. X——'s mother was one of twins. A sister of Mrs. X——'s father had borne twins.

As I have mentioned, Mrs. X—— was delivered of twins once, then she had an abortion at an early period of gestation (probably about three months), and, so far as I remember, her third confinement was with the hemicephalus. The birth of the latter took place somewhat more than a month before the regular term. It may be interesting to note some details of the confinement.

At the beginning of labor examination revealed an enormous quantity of amniotic fluid. No heart-sounds were to be heard in spite of thorough auscultation. The position of the fœtus could not be made out with any degree of certainty. On introducing two fingers into the uterus one could feel a hard and sharp prominence protruding during the uterine contractions, and receding after relaxation of the latter. Examination post partum proved this protruding part to be a sort of promontory (Fig. 2), forming the transition between the uncovered base of the skull and the vertebral column. Twelve hours after this first examination the described part was still floating quite loosely over the entrance of the pelvis; the water had not yet broken. As the external orifice of the uterus was sufficiently wide to admit the passage of the fœtus I deemed it expedient to relieve the patient's acute sufferings by manual extraction of the fœtus. The membranes were broken, which caused a torrent of fluid to break forth, a foot was seized, and the fœtus extracted. It was then put into a two and a half per cent. watery solution of carbolic acid, which has the advantage of preserving the color and gross anatomical structures, especially the skin, and of not causing any shrinkage. On the other hand, it has the disadvantage of spoiling the specimen for microscopical examination, at least of certain tissues—for instance, nervous tissue.

FIG. 1.

Fig. 1 is a photograph which gives a front view of the fœtus. It demonstrates a nearly perfect double formation of the face: four eyes, two noses, two mouths, two chins, but only one ear for each face. The two mouths are separated by means of a skin-bridge which continues backward as a probably cartilaginous septum reaching nearly but not quite to the posterior wall of the pharynx, so as to leave a communication between the pharynx corresponding to the right and that corresponding to the left face. Each mouth presents a well-developed tongue, a hard palate, and a distinct horseshoe shaped outline or impression of the superior and inferior alveolary processes. It seems also as if there was one soft palate common to both faces; at least a structure like anterior and posterior pillars is seen on the external side of each of the communicating pharynges. Attempts to find out whether the œsophagus was single or double were not successful. The sound did not pass beyond the pharynx or it came out at an opening in the base of the skull, which will be mentioned later.

Chins.—The two chins are separated by a slight vertical ridge formed by an elevation of the skin. Two separate lower jaws are distinctly felt; the medial branch of each can be followed by palpation some distance backward. Each jaw can be moved upward and downward separately—that is, independently from the other—which proves that they are not united further backward.

Ears.—There is one ear corresponding to each face situated on the lateral sides of the head, in normal position with relation to the latter. The right one looks much like the cropped ear of a dog, the left one, aside from having an abnormally large tragus, is well developed.

Strictly speaking, there is no formation that could be called a neck. The head, with the two faces, sits directly on the body, the ears rest upon the shoulders so that the tip of the left ear is turned outward and upward from the pressure of the left shoulder. In front the skin, instead of receding backward to display the inferior surface of the chins, passes straight from the anterior surface of the latter into the skin of the chest. It is thus difficult to state with certainty whether any formation corresponding to the larynx exists. No such formation can be made out by inspection or by palpation. Further down there is no double formation, at least not outwardly; two arms, one body, two legs.

Arms.—Perfectly well developed, including nails, fingers, hands, forearms, arms; shoulder-blades, and clavicles. The latter, however, seem to terminate loosely with what should be their sternal end, instead of articulating with the sternum.

Chest.—No sternum, at least no osseous sternum, is present. All ribs can be felt ending free anteriorly, thus leaving an anterior gap in the skeleton of the chest which widens in a downward direction, measuring about one and one-fourth inch in width at the level of the first ribs and about two inches at a level at which the processus xiphoides would be situated under normal circumstances.

Pelvis.—The left and right half of the pelvis are loosely connected; they can be freely moved from and against each other on the longitudinal axis of the body.

Lower Extremities.—I cannot state whether the abnormity of shape is due to misformation or to distortion caused by the manipulations of extraction of the fœtus. I am inclined to think that originally the lower limbs were not deformed.

Genitals.—Well-developed scrotum and penis. Testicles in normal position.

Posterior Aspect.—Fig. 2 is a photograph giving a view of the back and of the base of the skull. The photograph shows that the skull and vertebral column have remained unclosed. There is rhachi-schisis of the whole vertebral column, involving also the os sacrum. The edge (*vide* Fig. 2, No. 9) of the large gap in the median line is formed by the processus spinosi of the vertebræ, which, having remained ununited, have a transversal position; that is, the position which under normal circumstances is occupied by the processus transversi. To

demonstrate this condition clearly the periosteum was removed from the left side of the cervical portion of the spine, thus displaying the bodies of the vertebræ

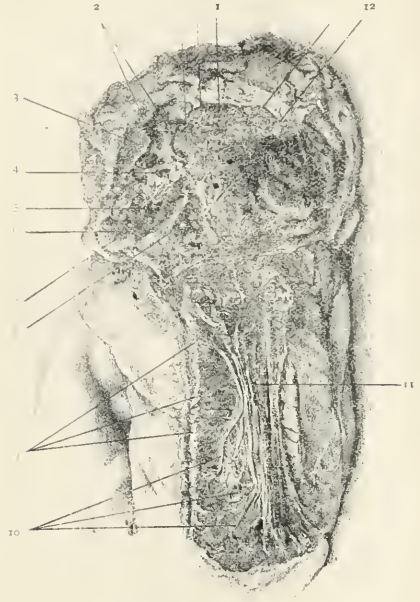

FIG. 2.—1. Opening communicating with the pharynx; 2, anterior clinoid processes of left sphenoid bone; 3, rudiment of temporal bone; 4, internal auditory meatus; 5, foramen lacerum posterius; 6, occipital part of left occipital bone; 7, anterior condyloid foramen; 8, posterior condyloid foramen; 9, spinous processes; 10, cauda equina; 11, spinal dura mater; 12, promontory.

and the processus spinosi. Fig. 3 gives a view of one cervical vertebra, showing the processus spinosi directed transversely, while the processus transversi occupy a dorso-ventrad position.[1]

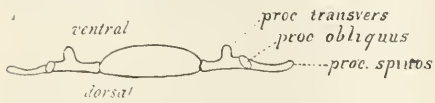

FIG. 3.—Cervical Vertebra.

The large gap mentioned is covered by a membrane which cephalad passes into the dura mater cerebri and must therefore be considered as the dura mater spinalis. At the caudal end and also in the upper part of the back this membrane passes directly into the mesodermal layer of the adjoining skin; in other regions this connection is torn. At the caudal end fibre bundles are seen eradiating from the dura mater in a latero-caudal direction and entering under the periosteum of the vertebræ. The arrangement of these bundles is quite analogous to that of the cauda equina. Similar bundles are seen all along the vertebral column; only the more cephalad they are situated the more horizontal is their course. This arrangement of the said bundles and their soft consistency makes it certain that they are rudiments of root bundles of spinal nerves. Histologically this could not be decided, as the preservation with carbolic acid solution made the nerves unfit for microscopical examination. I have used the expression "rudiments" because the bundles are much thinner than, comparing them with the calibre of normal spinal roots, one would expect them to be. Of the spinal cord nothing is present; probably it was destroyed a long time before the birth of the fœtus, which would explain the rudimentary appearance of the spinal nerve-roots.

Skull.—As before mentioned, the base of the skull was found uncovered. This was at least the case with the petrous portions of the temporal bones and the parts situated caudad of them. The parts cephalad of the petrous bones were covered with rudiments of frontal, parietal, and temporal bones. These were in close contact with the underlying bones of the base of the skull, so that only a narrow slit corresponded to what normally would hold the frontal, parietal, and temporal lobes of the brain.

Dura mater present but defective, torn (probably, at least partly, by the manipulations connected with the extraction of the fœtus) so that one cannot make out by its shape whether it held two separate brains or only one. Rather large pieces of brain were found in the dura, but so crushed that shape and structure were lost.

To get a view of the bony structure the periost was removed from the base of the skull. The first thing that strikes one's attention is a kind of promontory, situated at the distal end of the base of the skull forming a direct transition from the latter to the vertebral column (Fig. 2, No. 12). This promontory bears a rather close resemblance to a sacral bone. Like the latter it is curved, both longitudinally and transversely, the convexity of the curve being directed dorsad. Its proximal end is rather wide in a transverse direction; caudad it somewhat increases in width, being widest at about the middle of its longitudinal extent, from which point it becomes narrower and terminates with a narrow median ridge at the distal end. The median part of the promontory is occupied by a torus which passes through its entire length. In a transverse direction this torus has semicircular shape, in longitudinal (cephalo caudad) it looks conus-like, the base of the conus being situated at the proximal end; only, as I mentioned before, this conus shows a strong longitudinal curve, the convexity of which is directed dorsad. On each side of the torus there is a longitudinal row of four foramina. These are separated from each other by transverse ridges. Most of the latter have preserved a distinct individuality, as at their lateral ends they are separated from each other by a thin cartilaginous layer or joined by osseous suture. In two of them the lateral ends are melted into one coherent mass of bone.

All parts mentioned so far show complete ossification, the lateral border of the promontory, however, is formed by cartilage. At the proximal end the torus has a wart-like process (Fig. 2, *W*); ventrad from this there is a round opening of about 1½ mm. in diameter. A small sound passed through this opening comes out at the most distal of the foramina of the left side. Since some force has to be used, however, to pass the sound it remains doubtful whether this communication is a natural canal or an artefact. In passing the sound slowly through this canal the inner (ventral) surface of the torus can be distinctly felt as presenting several transverse elevations alternating with transverse depressions. The ventral wall of the canal seems to be formed of cartilaginous tissue. Distally this tissue seems to pass directly into the body of the first cervical vertebra, which (viz., the body) is still perfectly cartilaginous on its dorsal surface.

Of the lateral and proximal connections of the promontory I shall speak later.

There is no doubt from the structure of this promontory that it is a vertebral formation composed probably of four vertebræ. It remains to explain the significance of its various parts. One explanation would be that the vertebral canal has remained open, in which case the longitudinal torus would correspond

[1] I take opportunity to mention here that I shall by preference avail myself of the expressions "cephalad" and "caudad," or "proximal and distal," and of the terms "ventrad dorsad" to designate the relative position of the parts instead of using the terms "anterior, superior, posterior, inferior," which are easily misinterpreted.

to the bodies of vertebræ, while the transverse ridges—analogous to the condition of the other vertebræ—would represent the processus spinosi directed transversely, instead of dorso-ventrad as they should be under normal circumstances.

The second explanation would be that the vertebral canal is closed, that accordingly the longitudinal torus represents processus spinosi grown together to one solid mass of bone, while the transverse ridges between the foramina correspond to processus transversi, the bodies of the vertebræ being formed by the cartilaginous tissue situated ventrad from the longitudinal canal mentioned.

The following points speak in favor of the second explanation :

1. The bodies of the vertebræ of the cervical part of the column (probably also those of the other vertebræ, but these were not examined in order not to spoil the specimen) are still cartilaginous, while the longitudinal torus of the promontory is perfectly ossified. This fact makes it very improbable that the torus should correspond to a row of bodies of vertebræ. On the other side—analogous to the bodies of the cervical vertebræ—the tissue ventrad from the longitudinal canal of the promontory is cartilaginous.

2. The processes of the cervical vertebræ are ossified, as is also the longitudinal torus. The hypothesis that the torus represents processus spinosi grown together to one mass of bone receives still more support by this fact.

3. If the longitudinal torus is actually composed of a series of processus spinosi a canal corresponding to the vertebral canal must exist ventrad from the torus. Such a canal is, indeed, present, but as I mentioned before the possibility of its being an artefact cannot be positively excluded.

Although the facts mentioned make the second explanation very probable, I cannot arrive at a definite conclusion on the point. I feel satisfied, however, that the structure which I have called promontory is a formation composed of several, probably four, vertebræ. From the description given the peculiar similarity which this formation bears to a sacral bone becomes apparent.

I first thought that the structure in question might be the modified upper part of the cervical portion of the spine, but found proof that this is not the case. After finding out which vertebra corresponded to the first rib, and which consequently must be the first dorsal vertebra, I counted upward, with the result that there were seven processus spinosi (cervical) between the formation designated as promontory and the first dorsal vertebra. This proves the promontory to be a vertebral formation *per se*.

Proximally from the described vertebral formation, and directly connected with the proximal part of its lateral borders, we find on each side a bone of more or less rectangular shape. The longitudinal axis of this rectangle is directed from backward inward to forward sideward. It (the rectangular) is divided by an osseous suture into an anterior (*A*) and posterior (*B*) part (Fig. 2, *A* and *B*). Between the rectangular bone of the right and that of the left side we find a hole which has the shape of an equicrural acute-angled triangle, the crura of the latter being formed by the rectangular bones (*A* + *B*) of each side, while the base is situated cephalad. The said triangular hole opens directly into the common pharynx. Originally it was covered by a thick layer of periosteum, which I had removed in order to get a view of the osseous structure of the base of the skull, and which contained an osseous nucleus.

The lateral borders of the bones *A* and *B* of both sides are connected by cartilage with the petrous and occipital bones.

Occipital Bones.—They are represented in two halves, one corresponding to the right, the other to the left face. These halves are separated from each other by the promontory described, and by the bones *B*, unless we consider these to form part of the occipital bones. Each half shows a well-developed condyloid portion and a rudimentary occipital part. If a basilar portion exists, we must consider it as represented by the bone *B* plus the partly ossified periosteum which covered the triangular hole mentioned above. This hole, it will be remembered, opens into the pharynx, and the fact that under normal circumstances the basilar portion of the occipital bone forms the roof of the pharynx speaks in favor of said supposition.

The occipital portion of the occipital bone is represented on each side by a small bone situated laterally from the condyloid portion, connected with the latter by a strip of cartilage, while cephalad it joins with the petrous portion of the temporal bone. Its posterior border in line with that of the condyloid portion forms a curve, the convexity of which is directed caudad. The condyloid portion is well-developed ; it has a well-marked condyloid process—which of course cannot be seen in the photograph, but is found on lifting the bone—and both an anterior and posterior condyloid foramen. The foramen occipitale magnum does not exist, as the parts situated caudad from the foramen condyloideum posterius, which under normal conditions close the circle forming the foramen occipitale magnum, are absent.

Petrous Portions of the Temporal Bones.—There are two petrous bones, one corresponding to the right, the other to the left face. Posteriorly they are connected with the left and right half occipital bone respectively ; medially each joins the bone *A* of its side ; cephalad they connect with the sphenoid bones. Both petrous bones have a peculiar shape, due evidently to incomplete ossification. Aside from the meatus auditorius internus we find laterally, and somewhat cephalad from the same, a rather large, funnel-like foramen or fossa, which can be traced only a short distance inward and seems to end blindly. In position it corresponds to the region where we would expect the space between the three semicircular canals, and the most plausible explanation is that ossification has not progressed sufficiently to fill up this space with bone. We further find distinctly marked the aquæductus vestibuli and cochleæ, the Fallopian canals, and the foramina laterum medium and posterius.

Sphenoid Bones.—The bones described so far were single. There were two petrous portions of temporal bones, and two half occipital bones, just as in a normal skull. With the sphenoid bones the duplication begins. We see two sphenoid bones, each composed of a body and two greater wings ; the lesser wings are absent. The two sphenoid bones meet in the median line of the skull by connection of the medially situated greater wings of each. This connection is marked by osseous suture in the distal part, by a vertical crista in the proximal part. Quite near this crista, one to each side of it, there are two foramina, which in shape and position correspond to the foramina rotunda. A short distance caudad from these there is another pair of foramina which, although small, must be considered as the foramina ovalia from their position. These two foramina (ovalia) are joined by a rather deep groove which, crossing the median line of the skull at a right angle, passes from one foramen to the other. The distal border of the joined medial greater wings of both sphenoid bones forms the proximal border of the trigonal space which opens into the common pharynx. Two small incisions of this border may perhaps represent the rudiments of foramina spinosa.

It is seen from the above description that the extreme corner of the medial ala magna of each sphenoid bone is absent. With the lateral greater wings this is not the case ; they are complete and of approximately normal shape. The foramina rotunda and ovalia are well marked ; the foramina spinosa cannot be identified

with any degree of certainty. The body of each sphenoid bone is rather well developed, but without the posterior clinoid processes. The olivary process has an olive shape, only its longitudinal diameter is directed sagittally (cephalo-caudad) instead of transversely, as it ought to be. The processus clinoidei anteriores appear like rings attached to the body. The openings of these rings correspond to the optic foramina. No smaller wings are present, for which reason the sphenoid (orbital) fissures, instead of forming actual (narrow) fissures, appear as large, irregularly circular openings.

I have mentioned already that the frontal, parietal, and temporal bones are but rudimentarily developed. I must state, however, that of the two frontal bones only the posterior part is absent; the anterior part, including the orbital plate, is normally developed; there are four well-developed orbitæ.

In summing up we find the following conditions to be present:

1. Duplicity of the face and anterior part of the head. The duplication begins proximally from the petrous portions of the temporal bones, including thus the sphenoid, frontal, nasal, supra-maxillary, and infra-maxillary bones. Two pharynges are present, which communicate with each other.

2. Cranio-rhachi-schisis involving the entire vertebral column.

3. Interposition of a peculiar os sacrum-like vertebral formation and of two longitudinal bones (each of these again divided into an anterior and posterior part) between the occipital and petrous bones of each side. In proximo-distal direction these intercalary formations form the transition between the base of the skull and the vertebral column.

4. Absence of the sternum (at least of an osseous sternum).

According to the classification and nomenclature adopted by Ziegler[1] and Marchand[2] the monster described belongs to the group of diprosopi. It must be designated as a diprosopus diotus, tetrophthalmus, distomus, with cranio-rhachi-schisis involving the entire vertebral column.

THE THERAPEUTIC VALUE OF WATER IN THE TREATMENT OF SOME NERVOUS AND MENTAL CONDITIONS.

By HORACE PHILLIPS, M.D.,

PHILADELPHIA, PA.

ASSISTANT PHYSICIAN PENNSYLVANIA HOSPITAL FOR THE INSANE.

One of the earliest references to the strengthening effect of the bath seems to have been made by Homer, when Ulysses visited the king of the Phæacians (Alcinous) and was conducted to a bath, that he might regain renewed strength after his journey. The heroes of the Olympic games were accustomed to take cold baths in order that they might be better able to contest for the honors of the field. Plato prescribed the bath as a means of preserving the health and preventing disease. Hippocrates, in his treatise on "Air, Water, and Locality," divides the causes of disease into climate and diet, and practised bleeding, cupping, cauterization, auscultation, and bathing. Asclepiades, of Bithynia, who appears to have been a man of rather limited science and skill, forsook the general methods of the practice of medicine in his day, and relied entirely in the treatment of his cases upon the therapeutic action of the bath, exercise, and regulated diet. Later, Galen, during the second century, seems to have recognized the possibilities of water in the treatment of disease, and incorporated it as one of the recognized methods of treatment.

The public baths at Pompeii, though that of a provincial town, and inferior in size to those at the capital, occupied a piece of ground embracing an area of ten thousand square feet, and consisted of ten distinct establishments, the smaller of which is believed to have been devoted exclusively to women. In the larger was a court, bounded on two sides by a portico, which was used as a waiting-room for those seeking admission to the thermæ. From this space a communicating passage admitted to a smaller room, where the clothes of the bather were left (apodyterium); from this a door led to an apartment in which was the frigidarium, or cold bath. A pool in the centre of this apartment was of white marble, circular in shape, twelve feet in diameter and three feet in width, the water being conducted into the side of the pool by a bronze sprout, and in the bottom an outlet, which served to empty the bath.

From the frigidarium a door opened into a smaller room, which was warmed by a large portable fireplace, and here those who wished to use the warm bath were anointed and rubbed by attendants previous to entering the caldarium. The floor of the caldarium was placed on small pillars so that the heat from the furnaces had free admission beneath it. At one end of this room was placed the hot bath, which consisted of a shallow cistern $15 \times 4 \times 2$ feet in depth. Inside the bath, and along the rim, was a seat upon which the bathers might sit; the warm water was furnished from caldrons communicating with the bath by pipes. At the far end of the room was a huge vase, from the centre of which projected a spout, throwing a stream of cold water, which was designed to fall upon the head and shoulders of the bather previous to his quitting the heated atmosphere of the caldarium.

The great thermæ constructed by the Emperor of Rome were very elaborate and expensive, but constructed on the same general plan as that just described. Those of Caracalla were perhaps most famous, being fifteen hundred feet long by twelve hundred and fifty feet broad, and having, in addition to the usual apartments, large open spaces for exercise and covered courts which might be used for the same purpose during inclement weather.

The use of the cold or hot bath was regulated by the direction of a physician or the inclination of the bather. Previous to bathing it was customary for gentle exercise to be taken; then the bather passed, after denuding in the tepidarium, to the caldarium, and after waiting for a short time, immersed himself gradually in the hot water, or had it simply poured over his head and shoulders. Then he had a douche of cold water, and left this apartment to pass into the frigidarium, where he took a cold plunge. He was then scraped with strigils (small curved instruments), dried by being rubbed with linen cloths, and finally anointed; then, after resting in the adjoining room, he was ready to undertake the duties of the day.

When only one bath was desired, it was taken shortly before the principal meal, although under the direction of a physician, or when suffering from slight bodily disorders, it was not uncommon for four or six baths to be taken during the day. Commodus is said to have indulged in as many as seven baths a day.

The Turks and Arabs had, after the decline of Roman civilization, more particularly cherished the custom of bathing than other nations; and by the laws of Mohammed, as laid down in the Koran, all true believers were obliged to recite five prayers daily, and either to bathe or to wash their hands, feet, and face before each prayer.

Long after the fall of the Roman Empire the bath was retained, as is witnessed by the splendid remains which exist in Barcelona and Granada, and which were

[2] Realencyclopaedie der gesammten Heilkunde, vol. 13, under the heading Missbildungen.

constructed and used by the Moors previous to their conquest by the Spaniards.

During the period of the Dark Ages the knowledge and curative action of the bath was prescribed and practised by such peoples as the Arabs, Indians, Japanese, and Moors, and through the agency of these last was the bath introduced to European nations during the revival of learning.

During the sixteenth and seventeenth centuries water seems to have again attained some recognition as a remedial agent, for we read of Ambroise Parè prescribing it in the treatment of various disorders which appeared among the troops of Henry III. During the latter portion of the eighteenth century and first half of the present century, the bath had been used and abused in many cases, especially in the treatment of insanity; for we read that it had been proposed to drive delirious ideas from the minds of the insane by this method, and ofttimes they were brought to the verge of dissolution by prolonged submersion. Another favorite method was the cold douche, where the patient was subjected to extremes of temperature, often resulting in pronounced rigors or loss of consciousness. Such radical treatment was, however, soon recognized as questionable and was succeeded, after a careful study of the influence of heated water upon the human organism, by the more modern and scientific administration of the bath.

It is essential in studying the action of the bath upon the system that we study that force which the water, or whatever media we use, conveys to the human economy, namely, heat in its different varieties and intensities. The well-known fact that water requires more heat to warm it, and gives out more units of heat in cooling over a given range of temperature, makes it invaluable in bathing.

Heat when applied to the surface of the body in this manner, as stated by Dr. Parke (98° to 112° F.), is said to produce at first an inconvenient and then a painful sensation, due to the determination of the blood to the surface, which soon becomes swollen and reddened, the face turgid, eyes injected, action of the heart increased, and full and frequent pulse, with a sensation of dizziness and vertigo; the carotid arteries in particular beat with violence, the breathing is oppressed, and there is a painful sensation of weight about the head. Soon parts of the body not covered by water break out in a profuse perspiration, which only partially relieves the discomfort of the patient. On leaving the bath the excitement does not subside; the pulse continues to beat with force and frequency, the extremities remain swollen, the patient perspires profusely, and the secretion of urine is diminished. There is now a sense of muscular fatigue, and the whole system is relaxed and weakened. Physiologically we seem to have a partial paralysis of the vaso-motor system, with a consequent dilatation of the whole capillary system, an increased pulse, which becomes less tense and more rapid, due to a fall of blood-pressure from withdrawal of blood from the deeper structures, a general condition of passive hyperæmia, with a decided increased activity of the skin; the urine is found to be scanty and containing a lessened amount of urea. The temperature of the body will be found to have increased while the patient is in the bath, but on withdrawal the temperature rapidly falls, due to the increased area of blood exposed in the congested vessels.

The degree of heat at which coagulation of the blood in the arteries is said to occur is $42\frac{6}{10}$° C., which temperature, if not fatal, produces fatty infiltration and degeneration of the liver, heart, kidneys, and muscles. To man 100 to 132° C. in air proves dangerous and ofttimes fatal, and a temperature several degrees lower would probably have the same effect in water.

The degree of heat, as furnished by the hot bath, which would be fruitful of therapeutic action would, in view of the influences which we learn that it produces upon the body, range between 98° F. and 128° F. It needs no demonstration to state that a greater degree of dry heat will be tolerated by the system than that conveyed by water. The Japanese have been for ages accustomed to bathing in water heated to a temperature of 128° F., and to remain in such a bath for a period of from three to five minutes, the parboiling process which they thus undergo seeming to cause no apparent injury, and being stated to have a beneficial effect upon persons suffering from rheumatism and various skin diseases.

Let us next consider what are the effects produced by a less degree of heat upon the system when applied to it by means of the bath, as that produced by the cold or cool bath (32° to 70° F.). Dr. Forbes has described the sensation produced by such a bath to be as follows:

"On plunging into the cold water the bather experiences a sensation of shock, varying in intensity with the temperature of the water, which may amount to a rigor, with a sudden catching of the breath, drawing up of the limbs and arms, caused by the sudden contact of the cold fluid with the surface of the trunk and face. In some persons this spasmodic anhelation is so great as to entirely prevent speech. The surface appears contracted and shrunken, the superficial veins become smaller and disappear, the hue of the skin assumes a bluish tinge, and after a short time, which depends partly upon the coldness of the water and partly upon the constitutional vigor of the bather, reaction takes place, the chilliness and rigor disappear and are succeeded by a sensation of warmth which diffuses itself over the whole surface. The respirations become tranquil, and there is a general feeling of lightness and vigor. After a variable period, the bather again begins to suffer from the cold; trembling and rigor supervene, the movements become impaired and feeble, the pulse smaller and less frequent, the respirations are oppressed, and the whole body is languid and pulseless. If he leave the water before the occurrence of the second period of rigor, there is a renewal of reaction; a glow pervades the surface; the color returns and is heightened; the pulse is stronger and fuller than previous to the submersion, and there is a general feeling of buoyancy and vigor."

The physiological effects upon the vascular and nervous system produced by the application of cold are, first, a stimulation of the vaso-motor system and exaltation of the spinal reflexes, with a contraction of the terminal blood-vessels, slowing of the current of blood, a diminution of the number of corpuscles, and a gradual paling of the tissues. The corpuscles become less transparent, and finally their movement ceases, the vessels becoming blocked. Dilatation then ensues, due to a partial paralysis of the vaso-motor system, with an accumulation of blood in the terminal vessels causing a cyanotic condition of the surface. This condition may reach the deeper-seated vessels, but after a time causes an increased resistance which may be demonstrated by the sphygmograph.

The pulse, under the influence of cold, falls quite perceptibly, due no doubt to the stimulation of the inhibitory cardiac nerve, associated with a decided fall in the blood-pressure. The respirations are lessened in frequency and become more slow, the secretion of urine is scanty, and the liver and deeper structures become congested. The hyperæmia which is noticed in the cyanotic condition does not cause exudation. The temperature of the surface will be found to have fallen in proportion to the degree of cold and the time in which it is applied. The loss of heat following a continued application of cold causes a decrease of temperature chiefly by conduction, notwithstanding that at the same time there is an increased production of heat in the body; but the peripheral circulation being slowed, not so great a supply of blood is exposed to its influence, and an internal temperature will show

but slight decrease of heat. Following this retardation of the peripheral circulation, there is a paralysis of the sensory nerve-filaments; the pulmonary circulation becomes impeded, diminished oxidation of the blood occurs, and the vital centres become affected, producing loss of muscular power and sleep, deepening into coma.

What has been stated by Liebermeister as "the primary after-effect" occurs shortly after the body has been in contact with a cold media. The surface which has been blanched and reduced in temperature now becomes pink, and in withdrawal from contact with cold, assisted by friction, assumes a red and glowing appearance. The current of blood in the capillaries is accelerated: the blood-pressure rises; the pulse becomes fuller and stronger, showing an increased action of the heart; the respirations are now deep and full, and the spinal reflexes become less excited. The sensory nerve-filaments resume their activity, the skin becomes reactive and moist, the bodily temperature increased, and we have all the conditions of a healthy reaction established. The time at which reaction takes place is variable, usually being more prompt when exercise is conjoined with bathing, when a lower temperature can be borne than under other circumstances.

M. Roustan has stated that after a plunge in the Seine at a temperature of 43° F. he was unable to remain longer than six minutes, and reaction did not take place until that same night, after many hours of great discomfort, together with feeling of pain and weight in his head.

The deductions to be drawn from the effects just considered of cold baths upon the system would seem to be that low temperatures are better borne and the reaction more prompt when exercise, either by massage or muscular exertion, is practiced, but not being carried to the point of fatigue, for Dr. Patreizi has found that under the influence of cold the work of a muscle rapidly diminishes, being reduced as much as one-fourth of its normal capacity, the same being true of high temperatures, where he found that the blood in superheated muscles is no longer capable of histological exchange, and the toxic products act more energetically upon the muscle at such temperatures. No influences should be exerted which tend to demand of the system an increased local supply of blood, either physiologically or otherwise; hence no food should be taken before a bath. The same holds true of the use of alcohol or any stimulating substance previous to bathing. As the first effects of the cold bath tend to depress the vital powers, shock the nervous system, and decrease the bodily temperature, these conditions tend to call for extra exertion upon the heart, which has already been active in supplying a previous local demand.

In persons of tender years, as well as those advanced in life, cold bathing should be interdicted, also in cases in which organic disease of any vascular or excretive organs exist, as here reaction is slow and ofttimes imperfect. The warm bath (70° to 95° F.) embraces most of the beneficial effects which are derived from that of the cold bath with but few of its dangers, and lacks the debilitating and congesting effects which follow the use of high temperatures. In the warm bath we have a gentle stimulation of the peripheral circulation, no nervous shock, no alteration in the blood-pressure, an increased action of the skin and kidneys, with but little change in bodily temperature, and an action which will relieve a congestion of deeper structures by opening up new channels to a blocked circulation, with no cause for alteration in the functions of the vital organs.

Coming to consider the therapeutical action which the bath may have in that group of nervous and mental diseases which is characterized principally by marked changes in the circulatory system, one which would seem to be susceptible to benefit from the action of water is neurasthenia. This may be termed a condition where lack of tone, increased excitability, and a tendency to rapid fatigue, especially of the muscular system, are the chief characteristics. We would seem to have conditions which might be benefited by the bath, the loss of tone, brought about by imperfect nutrition in which the whole nervous system has suffered, and the vaso-motor system is prostrated and has become fatigued, which is demonstrated by the tendency to blush. This Beard has counted among the most characteristic symptoms of neurasthenia. In addition, the œdema of hands and feet, with rapid and transient changes of temperature in various parts of the body, hemorrhoidal and capillary aneurisms, bear witness to the general impaired condition of the vascular system.

Owing to the impaired physical condition of such patients, although cold baths would seem to be indicated, yet from the shock which would be consequent upon their administration, and failure under such conditions for reaction to be promptly established, they are contra-indicated. Tuke has stated that actually hot or cold baths should not be used in the treatment of this condition, but that moderately cold baths exert a beneficial action; also the vapor bath is beneficial in many cases. Massage should not be neglected in this connection, as the mechanical effect thus produced is a valuable adjunct to the therapeutic action of the bath. Ross states that he has found the thermal lime-baths useful in the treatment of neurasthenia, and does not recommend the use of cold baths.

In melancholia, where alteration in the general nutrition takes first rank as a physical symptom, we have as evidence of disordered circulation opaque and muddy skin, with impaired growth of its appendages, dry furred tongue, constipated bowels, a slow and soft pulse, and lowered bodily temperature, and in many cases œdema and cyanosis of extremities. Here the bath, by stimulating the peripheral circulation, establishing the normal action of the skin, and increasing the bodily temperature, either by reaction or direct heat, shows itself to be a valuable agent.

The warm bath is most generally applicable in melancholia where impairment of the functions of the skin and excretory organs are involved, while those cases exhibiting nervous excitability, with hypochondriacal notions, normal excretory organs, and pulse more rapid than usual, are most benefited by the cold bath or sponging.

Brierre de Boismont recommends the continued use of the warm bath with cold affusions to the head in melancholia, and states that he knows of no remedy which compares with prolonged baths and continued irrigation in the treatment of such cases. Clouston speaks highly of the Turkish bath in the treatment of melancholia, and when the hyper-action of the brain seemed to exercise an inhibitory influence on the cardiac nerve-innervation, causing small pulse, lowered arterial tone, and impeded capillary circulation, marked benefit was experienced.

In mania Bevan Lewis has noted disordered circulation as one of the bodily symptoms, in some instances showing itself by injection of the peripheral vessels of head and neck, and again by marked pallor of the face, associated with a small and frequent pulse and heart-sounds which are often muffled. Albutt has pointed to the anæmic condition of the optic disks (alternating with marked vascular suffusion, doubtless caused by spasm of the retinal vessels) as an important symptom in this disease. The headaches, sense of weight, and insomnia are ofttimes associated with an increased temperature, ranging to 100° F. In addition to these symptoms there is a furred tongue, either lost or perverted appetite, constipated bowels, a sluggish condition of the glandular system, and in some cases furuncles and whitlow are present in the acute form of mania.

Dr. Savage, referring to the pulse-tracings which he has conducted, states: "They bear a strong resemblance to those found in fever and acute diseases, but in maniacal tracings the rate is less and the heart more forcible." The skin, the urine, and general nutrition are also disordered, and add their quota to complete the clinical picture of the physical symptoms in this disease.

Acute delirious mania differs from the less severe form of the disease in that each symptom is intensified and is associated with a marked hyperpyrexia, complete insomnia, arrested nutrition, scanty urine, a dry brown tongue, and general condition of exhaustion, which is well expressed by the form typhomania. The adaptation of the bath as a factor in the treatment of mania must be modified to the exigencies of each case, and it is imperative that when such alterations of the vital functions exist as diseases of this character produce, radical and heroic measures should be avoided. It has been said that "some patients are mad from an excess of blood, others from a deficiency of blood," a statement which gives us a hint as to the dangers which we must combat in the treatment of this disease.

Clouston states that he has seen prolonged warm baths (99° F.) do good in many cases, and in some act like a charm. His usual plan of treatment was "to immerse the patient in the heated water and apply cold affusions to the head, the effect of this combined bath being to fill the capillaries all through the body and withdraw blood from the brain, to depress the heart's action, to soothe nervous irritation, and to produce sleep."

The more rapid capillary dilatation and consequent displacement of large volumes of blood from congested centres would seem to be more readily effected by baths of a higher temperature, but the determination of quantities of blood to the surface by this means has been found to be associated with results which are alarming, and at times deplorable accidents have followed this method of treatment. The shower-bath of a moderate temperature has been found useful, but here it should be remembered that sufficient physical strength must exist in order that reaction may be established, else the results may be harmful.

In the acute stages of general paralysis cold baths have been strongly urged by Voisin, particularly during periods of excitement with increased temperature. The baths were given at 60° F. for a period of ten minutes, the patient being well wrapped in warm blankets for an hour afterward, until the pale face, blue lips, etc., gave place to signs of complete reaction. It is claimed that the cold bath in such cases improves the general state, lowers the temperature, diminishes the tendency to bed-sores, and increases the mental reflexes, particularly if a stuporous or depressed condition exists. The warm baths are also recommended in chronic mania, dementia, and epilepsy, where they seem to have a tonic action by building up and improving the general tone of the system, and rendering the patient thereby less liable to succumb to intercurrent acute affections to which he might otherwise fall a ready victim.

Although the therapeutic action of the bath has been recognized for centuries, yet its application outside of sanitariums and so-called water-cure establishments has not become the factor in the treatment of disease which its importance and promise would warrant. There seems, however, by the general interest which this subject has recently awakened, and as evinced by the equipment of hospitals and other institutions for the treatment of chronic diseases with appliances for the proper administration of the bath, that careful and searching inquiry and experimentation will be made by competent scientific observers. And this remedial agent will erelong take its proper rank among the more important methods of treatment of chronic disease, which have hitherto been regarded as beyond the reach of medical science.

A REPORT OF A CASE INVOLVING THE QUESTION OF THE DIAGNOSIS AND OF THE PROPER TREATMENT OF APPENDICITIS IN PREGNANT WOMEN.

By J. W. THOMASON, M.D.,

HUNTSVILLE, TEX.

A CASE occurring in my practice recently was so interesting, not only from a general clinical standpoint, but particularly in its bearings upon the diagnosis and treatment of appendicitis in pregnant women, and upon the possibility of the confusion of that grave disorder with other pathological conditions, that I feel I may be excused for reporting it.

On the afternoon of April 3, 1895, a gentleman called at my office for a prescription for his wife, who, he said, was feeling a little indisposed, had some pain and uneasiness in her right side, and was constipated. He stated further that she had had no fever, and had been well until this time. Knowing the lady in question to be a stout, healthy young woman, I judged from his description of her symptoms that she could not be very sick, and so suggested a teaspoonful of compound licorice powder and a sinapism, to be followed by hot applications until pain should be relieved. I was called to see the patient at nine o'clock next morning (April 4th). She was a woman about twenty years of age, and just entering upon the ninth month of her first pregnancy. She stated that she had taken the purgative, but had vomited once or twice during the night, and it had not moved the bowels; that the hot applications had failed to relieve the pain which was located in the lower right side of the abdomen, and was constant. Upon examination, I found her temperature to be 104.4° F., and pulse 132 beats to the minute. There was no tumor or swelling discoverable in the right iliac region, palpation of which, however, was unsatisfactory, by reason of the abdominal distention due to the advanced stage of pregnancy; but the pain was constant, and most intense over the region of the appendix. Vaginal examination was negative; the child's head was so large and so low in the pelvis, that I could make out nothing further than the fact that there was no special tenderness anywhere on the right side of the pelvic vault. The patient stated that the course of her pregnancy had been uneventful, and her health, until now, excellent; that she had taken a walk on the day before, and had felt this pain come on rather suddenly as she was walking, and that she had not been free from it since. She could not say when the fever came on, as she had had no well-marked chill. The fœtus was alive and active. There was nothing unusual about its heart-sounds or about the placental bruit. No special tenderness of uterine walls, save near seat of pain in the right iliac region. No evidence of special trouble about kidneys or bladder. What then was the diagnosis?

Dr. J. B. Murphy, in an article published in the *Journal of the American Medical Association*, of March 23, 1895, states that the symptoms by which we may diagnosticate "appendicitis" with almost positive certainty are (to use his own language): "1, A sudden pain in the abdomen; 2, shortly followed by nausea and perhaps vomiting; 3, local tenderness over the side of the appendix, and most frequently in the right iliac region; 4, elevation of temperature."

I had read this article, and had had some experience, both surgical and medical, with appendicitis. I thought I could exclude everything else in this case, and so made my diagnosis accordingly. Many cases of appendicitis will recover by natural processes, and may be influenced favorably by medical treatment only. My own professional experience has convinced me of this fact, and that such is a common experience is one reason why surgical treatment is so often postponed longer than it should be. Then, too, de-

lay in these cases does not always prove fatal. A case reported by Dr. P. F. Mundé, in the MEDICAL RECORD of December 1, 1894, and now famous in medical literature, was of a woman, eight months pregnant, who was attacked with pain in right iliac region, fever, vomiting, and other symptoms of appendicitis, which were followed a week later by miscarriage and delivery of a dead fœtus. The appendicial abscess was only diagnosed on the day after the delivery, operation performed about six days later, and the woman made a good recovery.

On the other hand, operations for appendicitis in pregnant women, where such operations have been reported, seem not to have been followed by such results as would justify a practitioner in proceeding without hesitation to adopt surgical measures, to the exclusion of all other treatment.

In an article entitled "Gestation Complicated by Appendicial Abscess," by Dr. L. L. McArthur, of Chicago, published in the February, 1895, number of the *American Journal of Obstetrics*, the author reports two cases of appendicial abscess in pregnant women: Case I. was a woman aged thirty-one years, multipara, pregnant four and one-half months. Operation was performed on the third day of attack, abortion followed next morning, and death of the patient occurred on the second day after operation. Case II. was a woman aged thirty-four, tripara, five months pregnant, who had been sick three weeks before she was taken to the hospital, when diagnosis of appendicitis was made and operation performed a day later. Miscarriage occurred two days afterward and death on the fifth day after operation.

To illustrate the difficulty of absolutely accurate diagnosis in some of these cases, Dr. McArthur reports another case, where a woman aged twenty-three, after a long railroad journey and a week of "malaise," developed suddenly a temperature of 105° F., with vomiting and general abdominal pain which, after the second day, was most intense in the right iliac region. Several surgeons concurred in his diagnosis of appendicitis, and advised exploratory incision, which being made, threw no light on the cause of the symptoms, but exposed to view a normal condition of the appendix and abdominal organs generally. The patient aborted next day, giving birth to a macerated fœtus, and the author concludes that the symptoms were due to the irritation set up by the presence of this dead body in the uterus. This woman recovered, but was not a case of appendicitis.

In the discussion elicited by the reading of this paper before the Chicago Gynecological Society, no definite plan was agreed upon as the proper course to pursue in the management of these cases. It was brought out that the troublesome feature in dealing with them, was the fact that the pregnant womb generally forms one wall of the appendicial abscess. The disturbance to the uterus incident to opening, cleansing, and draining the abscess, is almost sure to cause it to evacuate its contents, and in so doing, it draws away from the new relations it has formed, tearing the adhesions which walled off the abscess, and permitting the escape of septic matter into the general peritoneal cavity. In view of these dangers, a member present suggested that the best mode of procedure in these cases, when operation seemed imperative, would be first to induce a rapid abortion, then to open, cleanse, and drain the abscess, and thus leave no opportunity for further peritoneal infection by assumption of new relations by that wall of the abscess formed by the uterus.

With these conditions before me I concluded to risk delay in my case and to await development for a while. Accordingly I prescribed for my patient one grain of calomel every three hours until six grains should have been taken, two and one-half grains of Dover's powder with every other dose of calomel, and one minim of tincture of aconite every hour until some reduction of temperature should be accomplished. At 4.45 P.M., temperature was 102° F.; pulse, 142. Patient still complained of constant pain in iliac region and now also in lumbar region, and pain intense on pressure over appendix. Aconite was discontinued and warm water enemata ordered; one now, one in three hours, and a tablespoonful of sulphate of magnesium to be taken at 6 A.M. to-morrow. It is of interest to note that a specimen of urine examined contained about one-sixth, by bulk, of albumin.

April 5th, 9 A.M.—Temperature, 99° F.; pulse, 112. Enema last night moved bowels and gave some relief to pain. Medicines have acted several times. Pain still severe in iliac region. 4.30 P.M.—Temperature, 102° F.; pulse, 124. Bowels and bladder inclined to be irritable; considerable pain in right iliac region intensified by pressure over region of appendix. No nausea or vomiting. Patient has taken small quantities of water and chicken broth during the day. I gave hypodermatic injection of morphine sulphate, $\frac{1}{4}$ grain, and atropine sulphate, grain $\frac{1}{150}$; ordered hot applications continued and thirty drops of laudanum by enema if necessary to relieve pain during the night.

April 6th, 9 A.M.—Temperature, 99$\frac{1}{5}$° F.; pulse, 120. Some irritability of the bladder during the night was relieved by the use of the laudanum enema, one time. Pain not so severe this morning, but still marked in the usual place. Hot applications continued; no other treatment. 4 P.M.—Temperature, 100$\frac{1}{5}$° F.; pulse, 120.

April 7th, 9 A.M.—Temperature, 99° F.; pulse, 118. Had a fairly good night, though suffered some pain and used laudanum enema once during the night. Pain still rather severe over appendix. 4 P.M.—Temperature, 100$\frac{3}{5}$° F.; pulse, 118. No special change in symptoms.

April 8th, 1.30 A.M.—Was called up at this hour and told that patient was restless and perspiring profusely. Almost sure that the dreaded rupture had occurred and that surgical measures could be postponed no longer. I found, upon my arrival at her bedside, my patient's general condition not at all unfavorable. Temperature had fallen to 96° F.; pulse, to 90. I am inclined to think that this was the crisis in this case. A dose of mixed bromides was the only sedative given and patient's temperature at 9 A.M. next morning (April 8th) was 97$\frac{4}{5}$° F.; pulse, 100. Still some pain, but only elicited by pressure over region of appendix.

April 8th, 4.30 P.M.—Temperature, 98° F.; patient cheerful and comfortable. The further progress of this case was without incident of importance. After April 10th, I discontinued my visits, temperature remaining normal, and there being but slight tenderness on pressure over appendix. Impressed with the gravity of the symptoms in the beginning, however, I felt that my patient would not be entirely safe until her confinement should have taken place.

The sequel was even more interesting than it promised to be. I was called again to this lady at 7 A.M., April 30th; found her in labor; presentation L. O. A.; temperature and pulse normal. Labor was natural, though severe and tedious, and delivery of a large healthy female child was accomplished at about 5.30 P.M., without even rupture of perineum. Proceeding to deliver the after-birth I remarked the position of the uterus which, contracted in a cylindrical roll, lay obliquely across the abdomen, seemingly drawn toward the right side. Upon expressing the placenta with one hand and receiving it with the other, I was struck with the hard, leathery feeling of its free surface and border, and the peculiar gritty sensation imparted by the part which had been attached to the uterine wall, and noted too that that attachment seemed to have been to the right side of uterus. Examining the placenta, I found its peculiar feeling to be due to its having undergone calcareous degeneration; its substance feeling like sand-paper; so thickly were the limy concretions dispersed throughout its tissues. The free surface was

of whitish appearance, showing here and there elevations resembling nodules of inflammatory lymph, while the large blood-vessels and their tract were enveloped in and covered with this yellowish white deposit of plastic material. The condition suggested was that of inflammation of the placenta, stopping short of formation of pus, but followed by calcareous degeneration.

Though my patient had had a temperature higher than that to which Dr. Mundé attributed the death of the fœtus in his case quoted above, and though this rare condition of the placenta is said to be one cause of the death of the fœtus in utero (Leischman), the child in this instance was very much alive, fat, and weighed eleven pounds. The fact that my patient's temperature after delivery was 102° F., caused me some little uneasiness; but the pain in the right side did not return, the fever had disappeared by next morning, and the lying-in period was uneventful. An examination a few weeks ago showed a very slight tenderness in right iliac region, but patient is up and seems in perfect health at this time.

I am not altogether satisfied as to the correct diagnosis of this case, the symptoms of which may have been caused by any one of at least three pathological conditions. They may have been due to appendicitis, and were certainly the symptoms usually considered pathognomonic of that condition; while the placental condition may have been the result of gradually progressive calcareous change, extending over a longer period of time than the twenty-seven days which intervened between the onset of this attack and labor. Or they may have been due primarily to "inflammation of the placenta," subsiding before pus formation and followed by the calcareous change, and not to appendicitis at all. Dr. McArthur's third case, quoted above, resembling this case in its features of high temperature, localized pain, and other symptoms of appendicitis, renders this second idea as to diagnosis of my case plausible. Or, finally, they may have been set up by an appendicial inflammation, the contiguous right wall of the uterus forming one side of the resulting inflammatory focus, and an extension of inflammation through the right wall of the uterus may have caused the changes found in the placenta, the original appendicial inflammation terminating either by resolution or by discharge of inflammatory products into the intestinal canal.

The prime object of this paper, however, is to solicit an expression of opinion as to the proper mode of dealing with appendicitis complicating pregnancy. When may we temporize? When must we operate? It seems to me that if we must operate upon these cases, the radical plan of first inducing abortion and then opening the abdominal cavity, is a rational plan; but it, too, must necessarily involve grave risks for the patient. Where the womb forms one wall of the appendicial abscess, and who can tell when this condition exists, to rid it of its contents and insure its safe contraction, would be to tear it from its adhesions about the appendix and to set free the contents of the abscess in the abdominal cavity. Some time must elapse between the induction and completion of the abortion and the opening of the abdominal cavity. The possibility of the infection of the general peritoneal cavity in this interval, however short it may be, is a dangerous flaw in this plan of treatment. Operation without first causing abortion proved fatal in the two cases published. Delay and operation after labor was successful in Professor Mundé's case. Delay alone is sometimes rewarded by the recovery of the patient.

The surgeon with large experience and abundant facilities may risk operation in these cases and view the results with equanimity, feeling that he has performed his duty in carrying out strict surgical principles; but the practitioner in small towns, where the welfare of every patient is a personal matter and fraught with anxiety and responsibilities to himself, must, in view at least of published results in these cases, hesitate before adopting radical measures of treatment.

PLASTIC OPERATION ON THE PENIS AND SCROTUM.

By H. C. HALL, M.D.,

TELLURIDE, COL.

C. E. R——, aged thirty-two, with fine physique and seemingly perfect constitution, no objective nor subjective symptoms of past or present venereal trouble; consulted me, January 28th last, with the statement that while at work in a stamp mill, four days before, the work being of a nature requiring great force to be exerted with his left leg, he was taken with slight pain in the left inguinal region, which increased gradually the following four days, when he was compelled to quit work. On examination I found a number of enlarged and inflamed glands in that region. The usual methods for the relief of such a condition were employed, but to no avail whatever. It pursued an indolent and gradually advancing course until March 1st, when there was sufficient evidence of suppuration in one of the glands to warrant an incision, which was made with the result of evacuating about an ounce of healthy-looking pus. Strict antisepsis was observed at time of, and following, the incision. The patient was on the street within two or three days thereafter, and continued to go about until March 13th, when, while sitting in my office, after having just remarked that he felt fairly well, he was seized with a most violent chill, lasting forty-five minutes. At the end of this time he was greatly prostrated, and vomited profusely, the pulse and temperature rising rapidly. The prostration continued, and at noon of the second day thereafter he directed my attention to an uneasiness, as he termed it, of the scrotum and penis. Examination revealed a beginning inflammation of the skin and subcutaneous tissues of those parts. By the evening of the following day they had attained to enormous dimensions, and by noon of the day after this, lines of demarcation were forming. Temperature above 104° F.; pulse rapid and feeble, and beginning delirium. The parts sloughed away and on the fourth day I removed all the sloughing tissue, as shown in Fig. 1.

FIG. 1.

As the destruction of the penis cannot be well seen,

I will state that two-thirds of its entire skin and subcutaneous tissue sloughed, leaving a strip, from base to apex, amounting to one-third. Improvement in the general condition set in from the date of removal of the slough. During the following three weeks, the testicles were kept well incased in oil-silk and absorbent cotton, at the end of which time their surfaces presented a healthy and granular appearance.

On April 11th, in the presence, and with the valuable assistance, of Drs. Brown, Tosh, Russell, and Litchfield, a flap of three and one-half inches in its greatest width, and six inches in length, with convexities to suit conditions, was dissected from the inner aspect of the right thigh, leaving a pedicle one and three-quarters inch in width, and a little above the level of the parts to be covered. After freshening and smoothing the edges of the remaining portion of scrotum, the flap was sutured to it, except a space of one-third of an inch at the furthest extremity of flap, which granulated incompletely. Direct union followed in the entire circumference.

On May 18th, five weeks from date of operation, the pedicle was severed and returned to its place. The cut surface of the flap being sutured to that portion of the scrotum beneath, which also united directly. Four weeks seemed sufficient to complete the union of the flap before severing the pedicle, but another week was added to insure absolute safety. At that time the penis was nearly covered in its entirety with new skin.

On May 20th the patient came to my office on crutches. The wound on the thigh progressed rapidly and well. On June 16th, when the photograph reproduced in Fig. 2 was taken, there was a space only one-

half inch wide unhealed, and this was closed on July 1st.

The patient is now in the East, and writes me that he is feeling quite well, and experiences little or no inconvenience from his late trouble.

A Diphtheria Laboratory in Paris.—A municipal laboratory for bacteriology has been established in the old Lobau barracks in Paris, where analyses of suspected cases of diphtheria are made within twenty-four hours after the materials have been handed in.

SYMPHYSEOTOMY.

By T. E. TAYLOR, M.D.,

DENVER, COL.

SINCE the recent revival of the almost forgotten operation of symphyseotomy a few years ago, the cases reported have multiplied, and the technique has been perfected, until we are rapidly getting into a position where we can define the limits within which it is justifiable. Until this is done every operation should be reported, as the larger the number of cases recorded the less is the likelihood of error. Having recently had a patient who was delivered by this means, I take this opportunity to report the case.

Mrs. G——, aged thirty-three, German, sent for me early in the morning of March 6th. I saw her at 7 A.M., and was told that she had had strong pains all night, labor having set in at 2 P.M. the previous day, and the membranes having ruptured at 10 P.M. I was also told that her previous labors had all been difficult, all of her four deliveries having been by craniotomy.

Upon making an examination I found the os thoroughly dilated, the vertex presenting in the first position, and the head so firmly crowded down into the inlet that I could not reach the promontory of the sacrum, though the ease with which I could reach the upper segments of the sacrum indicated that its promontory would be within reach were the head out of the way. Upon taking the customary external measurements I found the following dimensions: Spines, 10½ inches; crests, 9½ inches; extended conjugate, 6½ inches.

Two weeks after delivery I found the diagonal conjugate to measure three and one-fourth inches, giving me an estimated true conjugate of two and five-eighths inches.

Although satisfied from the measurements of the pelvis that there was no possibility of a head approaching the normal in size passing through it, this conclusion also being confirmed by the history of successive craniotomies, yet as the surroundings were most unfavorable for any operation, and as the patient was very averse to going to a hospital, or indeed to undergoing any operation at all, I put on the forceps to give her the benefit of any chance that the head might be small and compressible enough to pass through the contracted inlet. The forceps were applied without difficulty, but strong traction applied with remission for half an hour failed to produce any effect. It seemed evident, therefore, that an operation was inevitable, and she was persuaded to go to St. Luke's Hospital for this purpose, Dr. Parkhill being called to my assistance. Dr. Parkhill agreed with me that symphyseotomy was the preferable operation, though the conditions were not what we should have liked, as the woman had been in labor already twenty-four hours, and ten hours had elapsed since the membranes had ruptured, she being during this time in the care of a most ignorant and dirty midwife, who had made frequent examinations. I confess, too, that the preliminary application of the forceps, though authorized and even insisted upon by some, was hopeless and ill-advised, and had an unfavorable bearing on the prognosis. It must be remembered, however, that at this time I had not been able to measure the diagonal conjugate, and consequently could not know how great the contraction was, estimates founded upon the external conjugate being very unreliable.

At the hospital the abdomen, thighs, and vulva were shaved and thoroughly disinfected as for any operation, and the vagina was also thoroughly disinfected. Dr. Parkhill operated by the open method, dividing the symphysis from before backward with a bistoury. As so often happens, the symphysis was not in the median line but a little to the left. Upon dividing the symphysis the pubic bones separated about an inch and

a half, the separation as the head passed through the inlet reaching two and one-half inches. The labor was at once completed by the application of the forceps, only moderate traction being necessary. The child was asphyxiated, but it was soon resuscitated. The patient recovered without noteworthy incident, leaving the hospital on the ninth day, and within three weeks resuming her household duties and the care of the baby. There is no perceptible movement of the pubic bones, and her gait is as secure as formerly.

This result was very gratifying in comparison with the bloody record of four successive craniotomies. The question arises, Was it the best possible operation to do? At our meeting last year a successful case of Cæsarean section was reported, and to some it may seem that the latter is the more promising operation. Looking into the statistics of the two operations, we find that the results in both depend largely on the period covered and the operators concerned. If we go back fifteen or twenty years, before the days of aseptic surgery, and when the indications calling for them were not well understood, we find both operations alike unsatisfactory. To resort to them when every other hope has failed, and when the mother is already exhausted by a long and fruitless labor, is not fair to these operations, and the resulting mortality is not so much the mortality of the operation as the mortality of prolonged labor. The true mortality of symphyseotomy, as of Cæsarean section, must be computed from those cases alone where the measurements have been carefully taken, and the most suitable operation undertaken as a matter of election, not as a last resort, and where every precaution has been taken to avoid sepsis. Tried by this standard the earlier cases, down to 1880, must be rejected as a whole; and of the cases reported since that time, while the field of the operation was ill-defined, a large part, including most of the fatal cases, must also be thrown out, as they were either performed after labor had continued a long time, or the conditions were such as to make symphyseotomy unsuitable, or death was due to some complication unconnected with the operation itself. What the results of symphyseotomy, thus revised, may be are seen by the statistics reported by Spinelli in the *Annales de Gynécologie* and translated by Dr. E. Gustav Zincke for the *Ohio Medical Journal* for April, 1895, where, of twenty-three cases operated on by Morrisani, Novi, and others, all the mothers recovered and only one child died twelve hours after the operation. Similarly Grandin and Jarman state that of the four deaths occurring in thirty-one cases operated upon in the United States up to March, 1894, in not a single case was the operation elective, being only performed after the patient was already greatly exhausted; while of the nine fœtal deaths eight would not have occurred if the operation had been elective. Even the best statistics of Cæsarean section cannot equal these results, so that the conclusion seems warranted that when the pelvic contraction is not below the limits of successful symphyseotomy it is not only the less formidable operation to the patient, but it is really less hazardous. Beyond these limits the combination of induced premature labor and symphyseotomy is feasible, but will not usually give as good results as Cæsarean section.

The limits within which symphyseotomy is feasible are pretty well determined, extending from the limit of a safe delivery by forceps with a true conjugate of about three and one-half inches down to a conjugate of two and one-half inches. It is unsafe to allow the pubic bones to separate more than three inches, lest the sacro-iliac joints be injured, which gives us a gain of about three-fifths inch in the true conjugate; but as the transverse diameters are increased much more than the conjugate, there is plenty of room for moulding the head, so that the entire gain by the operation is equal to a gain of one inch in the true conjugate.

As to embryotomy, does it not seem that it is time to say that this operation is not justifiable if the child is living? Granting that we should attach more importance to the safety of the mother than of the child, when we have an operation that is as safe for the mother, and which usually saves the child, how can we hesitate as to our duty? Of course, the patient and friends must consent to the operation, and they may refuse to allow symphyseotomy, but this does not justify us in destroying the child, any more than her earlier preference for abortion would have justified us in resorting to this means for relief of the nausea of pregnancy, when not justified by the necessities of the case.

A CASE OF ECHINOCOCCUS CYSTS OF THE LIVER, PLEURA, OMENTUM, MESENTERY, PERITONEUM, AND BLADDER.

By HARLAN M. PAGE, A.M., M.D.,

HIRAM, O.

I was called, September 3, 1894, two miles into the country, to see a German woman, fifty-one years of age, the mother of two children, the youngest being twenty-one. She had always worked hard, in doors and out. She had a moderate appetite, slept well, menstruated regularly, and was not constipated. Two days before she had begun to have pain in the right hypochondriac region, and the dyspnœa, from which she had suffered more or less for five years, had increased. Had had slight chills. Seven years before she had noticed a small lump the size of a hen's egg in the right hypochondrium, which had gradually increased in size. She was in fair flesh, slightly jaundiced, with a very anxious and distressed expression. Temperature, 102° F.; pulse, 120 and feeble; respirations, 30. Tongue slightly coated. Examination of the chest elicited increased vesicular murmur on the left side. Apex beat in normal position. Dulness on percussion on the right side, with no increase of vocal resonance. Abdomen generally distended, with a circumscribed prominence in the right hypochondrium. Dulness marked from the clavicle on the right side to a line drawn between the anterior superior spines of the ilia, extending over the median line in the abdominal region. Palpation demonstrated fluid in the circumscribed prominence, and hard nodular masses throughout the remainder of the area. Examination per vaginam showed that there was no connection between the uterus and appendages and the mass above, although Douglas's cul-de-sac was full of nodular resisting material. I could not arrive at any reasonable diagnosis, and advised the patient's going to Cleveland for further advice.

At the end of four weeks, during which time the woman had suffered much from pain and dyspnœa, I was again summoned. I found all the previous conditions exaggerated, and in addition ascites and œdema of the ankles. They were now ready to follow my suggestion, and accordingly Dr. T. M. Sabin, of Warren, was called. We aspirated the circumscribed tumor above referred to for purposes of diagnosis, and brought to light fetid pus which we evacuated by means of an incision one inch in length. So great was the tension that the pus spurted at least three feet beyond the patient's body. We obtained in all about five quarts of pus and straw-colored fluid. In this we were surprised to find a large number of sacs filled with a yellowish fluid, and in addition a large opaque one which had collapsed as a result of the incision. As this did not escape last we were convinced that the container of all was yet within. We dressed with iodoform gauze and cotton, and left our patient much relieved as regards dyspnœa. At the next dressing I succeeded in getting out, by change of position, fully a quart of bile-stained fluid devoid of odor; this characterized the discharge to the end, suggesting the deodorant property of bile.

During the five days immediately succeeding the operation the temperature remained normal, the heart action was improved, and respirations became easy. She took considerable nourishment and seemed to be improving in every way until the sixth day, when she began coughing severely, and died on the seventh day, apparently from exhaustion.

I was compelled to make the post-mortem examination alone and on limited time, hence my observations were not as many or as accurate as the case merited. I found the pleural sac on the right side full of pus and the pus full of sacs such as escaped from the incised tumor. The lung did not seem to have been involved in cystic changes, but was compressed into a very small compass and hepatized. Much of the liver was involved, some of the cysts having undergone purulent transformation; others not. This condition was also true of the many found in the peritoneum, omentum, and mesentery. The intestines, and in fact all the abdominal viscera, were matted together. The uterus and appendages were demonstrably uninvolved, as were also the kidneys. In making my incision I tapped the bladder, and a large quantity of clear fluid escaped as though under pressure; following this came six or eight small opaque sacs about the size of marbles, and finally one capable of holding at least four ounces of fluid. My time was up, and I reluctantly withdrew from territory which certainly had many more interesting things with which to reward more careful investigation. I bore away with me several of the omental cysts and those from the bladder, in the contents of which I again found the hooklets of the tænia echinococcus, or at least felt sure that I did; and my faith was strengthened by Professor A. P. Ohlmacher, of Cleveland, O., who kindly demonstrated them. Here there was a clear case of echinococcus cysts of liver, omentum, peritoneum, mesentery, pleura, and bladder. As to the primary seat of the trouble we can only conjecture. As to the source of infection, it was undoubtedly from dogs, of which they always kept several about the house, and with whom they lived on very intimate terms.

The case would seem to me to be worthy of note: 1. On account of rarity, Osler having been able to collect only eighty-five cases in the United States and Canada. 2. In the very wide dissemination of the cysts. 3. In the fact that the patient was able to do hard manual labor up to within four weeks of her death. 4. The phenomena of disappearance of odor coincidently with the appearance of bile in the fluid from the sac incised ante-mortem. 5. In the fact that the temperature remained normal after the operation until death.

In connection with these last two the question has arisen in my mind, whether absorption of bile might not counteract the effects of inflammatory changes so far as temperature is concerned.

Risk of Operating without Consent.—An action involving a claim for £2,000 has been tried in Belgium, which is of considerable interest to surgeons. It appears that a lady who suffered from uterine hemorrhage was recommended by a consultant who was called in by her family attendant to allow the uterus to be curetted, to which she and her husband consented. When the operation was begun it was discovered that there was cancer of the uterus, and the operator and the family practitioner decided then and there to remove the whole organ, the result being that the patient died from hemorrhage. As neither the patient nor the husband was consulted about the hysterectomy, it was held by the court to be unjustifiable. The damages were, however, reduced to £200.—*The Lancet.*

Supra-pubic Cystotomy was first performed by Franco, in 1561.

Progress of Medical Science.

The Treatment of Nervous Disturbances of the Heart Resulting from Influenza.—Dr. Sansom advises as a routine practice the use of sulphocarbolate of sodium in doses of twenty to thirty grains, every two, three, or four hours, according to the severity of the case. The diet should be almost entirely liquid. Alcoholic stimulants should be administered with caution; champagne diluted with Apollinaris, or brandy in dessertspoonfuls every three or four hours with milk and soda-water. When the temperature rises above 103° F., quinine is the best antipyretic. Phenacetin or antipyrin gives comfort, but their action must be watched, as they sometimes increase the already profuse perspirations. Pains are best controlled by phenacetin or antipyrin, unless profuse perspiration or signs of nervous prostration are contraindications. In profound adynamia the writer knows of no more efficient remedy than musk in five-grain doses. The hypodermic injection of brandy, ether, or strychnine may be called for. During convalescence, for several weeks, the sulphocarbolate of sodium with Fowler's solution is to be given three times a day after meals, and the nasopharynx repeatedly sprayed with an antiseptic solution like the following: Camphor and menthol, of each twenty grains; pure carbolic acid, one-half drachm; parolein, four ounces. The signs and symptoms referred to the heart resulting from influenza in the author's cases were thus distributed: In 100 cases: pain referred to the heart, 23 cases; tachycardia, 37 cases; irregular heart, 25 cases; bradycardia, 5 cases; organic disease of the heart, 10 cases For heart-pain after influenza, complete rest, morphine hypodermically (one-fourth to one-third grain) with diffusible stimulants are the remedial measures recommended. Once the severity is mitigated, five grains of quinine dissolved in hydrobromic acid is preferable to morphia. For more continuous treatment of the early painful phase, sodium bromide (twenty grains) with Fowler's solution (three minims) three times a day after food is recommended. In some cases sodium iodide (five grains) is added with benefit. When pain is persistent, local treatment is useful. Mustard poultices sprinkled with tinctures of opium, belladonna, and aconite, give relief in some cases. In others a fomentation of lint soaked in a hot solution of sodium salicylate is very efficacious; or an ointment containing twenty per cent. of salicylic acid and ten per cent. of menthol in a fatty basis of lanolin and lard, may be rubbed in over the painful area. In more chronic cases small blisters prove efficient. In tachycardia, or palpitation following influenza, the writer considers digitalis and analogous cardiac tonics not only useless but dangerous. The mixture of sodium bromide with small doses of arsenic, as suggested for the treatment of the cardiac pain, is perhaps most generally useful. For the insomnia, chloralamide (twenty to twenty-five grains) at bedtime is regarded as the most useful and least harmful hypnotic. Opium, the author thinks, should be avoided or reserved for emergencies. For continuous tachycardia, a galvanic current from a Schall's four- or six-celled battery is recommended, the anode held over the nape of the neck and the cathode gently pressed into the groove of the neck outside the larynx. Abnormal retardation of the pulse-rate may be relieved by phenacetin and camphor, with local warmth and counter-irritation of the epigastrium and abdomen. Permanent bradycardia is serious. Tincture of belladonna (ten minims thrice daily), massage, and graduated muscular exercise are useful; but it must be realized that the condition of very slow heart is one of peril.—*The Practitioner.*

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

New York, September 21, 1895.

CHLORAL.

CHLORAL is usually considered to be essentially a hypnotic and sedative drug. It has, however, quite a number of other uses. In this city it has long been employed, in small doses, as a vaso-dilator, two or three grains being given, combined perhaps with iodide of potassium. Associated with this same drug, Dr. Pal finds it of service in bronchial asthma, and the same physician has found it effective also, in doses of 10 to 20 grains, in checking bleeding from the lungs. On the same principle, that is, on the principle of its acting as a relaxer of arterial tension, Dr. Cherchevsky has used it in small doses daily to counteract coldness of the feet and hands, which are so disagreeable symptoms in some cases of anæmia and neurasthenia. Dr. Pal has also recommended chloral hydrate as a laxative in various forms of chronic constipation, principally those of neuropathic patients. The dose here, however, is more than 20 grains, and, as the *Practitioner* truly says, the drug must be a dangerous one to use for such a purpose.

M. Spehn recommends chloral very highly as a local application for boils. He directs that the boil be kept covered with a tampon of cotton well soaked in a solution of chloral hydrate, glycerin, and water. The strength of the solution is about two drachms to the ounce.

A writer in the *Semaine Médicale* recommends chloral for children who are irritable and restless when suffering from scarlet fever. Another use of chloral is in certain forms of dyspepsia in which there is a sense of distention with pain in the neighborhood of the cardiac end of the stomach. This dyspepsia usually occurs in neurotic persons and may be termed a nervous type of the disorder. According to the *Therapeutic Gazette*, a little chloral hydrate (one or two grains) dissolved in peppermint water is of service here.

Chloral is recommended by Playfair, in his textbook, for dilating the rigid cervix, during the early stages of labor.

We are somewhat loath to give chloral any more prestige than it already has. Still we should add that it is a drug which has been shown to be of some service in epilepsy, and which is one of the sheet-anchors in acute alcoholism; but it is also a drug whose continued use, even in rather moderate doses, is sure to injure the patient eventually. Chloral needs always to be given cautiously at first, and never for prolonged periods of time.

BONE SETTERS AND NATURAL DOCTORS.

WE hear very little nowadays about natural doctors. The discoveries in the line of bacteriology and the improvements in methods of physical examination and surgical treatment have rather thrown this interesting class into the background. There was a time, perhaps, when some of these born artists could come into a sick-room and by simply looking at a patient make a diagnosis which was most satisfactory to the family by reason of the learned terms with which an apparent exact knowledge was clothed. In these times, however, patients prefer to have their urine examined by those skilled in chemical knowledge in order to say whether they have Bright's disease, and they prefer to have the heart or lung examined with instruments of precision rather than depend on the guess-work of the intuitive practitioner. That instinctive knowledge which made what used to be called the natural physician was in the main simply a knowledge of human nature combined with a good deal of self-confidence and practical sense. These are still valuable and essential parts of the physician's equipment, but to them have to be added the technical knowledge which enables him to select proper antiseptics in his surgical operations and to make a careful examination of all the organs of the body which can be reached by instruments of precision.

We have been led to make these observations by the perusal of an interesting article on the Sweet family of Narragansett, which recently appeared in the *Medical Tribune* over the signature of Dr. Alexander Wilder. Many of the physicians of the present day have heard of the Sweet family and their wonderful bone-setting gifts. Probably some of our older physicians have even come in contact with them, but they are to most of us little more than a tradition.

The original member of the family, we are told, was Captain Banoni Sweet, who had been a captain in the British service, and who after the Revolutionary War settled in Narragansett. His descendants continued to live in that neighborhood and followed various humble occupations, some of them being farmers, blacksmiths, fishermen, mechanics, and so on. Job Sweet, one of the descendants made his great hit by relieving Theodosia Burr, daughter of Aaron Burr, of a so-called dislocation of the hip which had baffled the skill of the New York and Rhode Island surgeons for a long time. The story of Dr. Job's trip to Boston, and the dramatic way in which he disconcerted the regular faculty by his marvellous manipulations of Theodosia's hip makes very interesting reading, but we can hardly regard it as historical truth. We have some suspicion that perhaps Theodosia had what in these later days would have been called a hysterical joint. However, Dr. Job got his reputation and his fee and went home to return to his ordinary avocations.

Job had a son, by the name of Jonathan, who was equally skilful, apparently, with his father, and there was a Dr. Sweet, of Fall River, who had a very success-

ful experience with the Philadelphia surgeons. In fact, the history of the bone-setting Sweets, as told by Dr. Wilder, does not reflect the greatest credit upon the skill of the eminent surgeons of Boston, Philadelphia, and New York.

The Sweets, we are told, abounded in liniments, tinctures, embrocations, and salves, prepared by themselves from the plants, roots, and bark of trees growing in New England. Their usual plan of operations seems to have been to place some emollient application upon the affected joint for a time, and then by a deft manipulation to set the bone back in its place. There is no doubt that they did possess a good deal of skill in this kind of work. After all, the setting of a joint is not a very complex mechanical problem, and a great many more people could set joints than do so now if they possessed the confidence of the patient and the confidence in themselves which the Sweets had. This family seems to have inherited a belief that they possessed some inborn gift by which they could see into the joints, and by which they were enabled to picture in their mind's eye in each case the exact position of the displaced parts. They apparently had a certain hallucination at the time of the operation, and saw in their minds, at least, an open, dissected joint before their eyes.

The occupation of the bone-setter is pretty nearly gone by reason of the greater intelligence of the people and the greater skill of the regular faculty. There are still a few people in the world who prefer to be treated by an old woman or a bone-setter when they have some serious ailment, but the number is extremely small and will probably grow smaller, though we would not venture to predict that either folly or bone-setting will ever entirely die out.

THE COMMITMENT OF THE INSANE.

Mr. Albert Bach, a lawyer of ability and standing, read an article at the recent Medico-Legal Congress upon the subject of the commitment of the insane, which has attracted the notice of some of our daily contemporaries. Mr. Bach, who is Vice-President of the Medico-Legal Society, and who has, no doubt, made much study of the question, thinks that the present method of committing the insane is not perfect, and that the imperfections lie in its not being safe enough; or, in other words, not provided with sufficient care against the commitment to insane asylums of sane persons.

At regular intervals for many years individuals have become alarmed over the possible commitment of the sane into lunatic asylums. The result of this agitation has been to secure close and careful restrictions upon the methods of commitment. The present New York law is one which, so far as the safeguards which Mr. Bach is alarmed about are concerned, does not much differ from that which has existed for a number of years, and which has given satisfaction in this and many other States where similar provisions have been applied. The practising physician and alienist, who are familiar with the workings of this law, find that it is quite rigid enough so far as the points criticised by Mr. Bach are concerned.

The trouble with him and with lay students of this subject generally, is that only one danger is seriously considered, namely, that of committing a sane man to an insane asylum. The much greater danger of allowing insane people with homicidal, suicidal, and criminal tendencies to go about at large is quite forgotten; and the result is that we have, every year, a certain considerable proportion of homicides committed by lunatics who would, no doubt, have been safely placed away in lunatic asylums, if it were not for this fear on the part of the public that a sane man may be considered insane.

We must confess that, judging from the expression of the opinion by alienists, the need of an amendment to the present law, in order to protect the public, does not really exist. There are certain defects in the law, but they relate rather to the forms and details of the commitment. Any plan to have the judge himself see the lunatic before he signs the paper is an impossible one, for many lunatics are quite unfit to be brought into the presence of the court; and so far as the appointment of a commission or a jury is concerned, in order to determine the sanity of the patient, this is already provided for by the present law.

THE DEAN OF NORWICH ON DOCTORS' BILLS.

The ancient city of Norwich, in England, is a pleasant place, in which many good people have lived—eminent divines, masterful surgeons, noted linguists, and handsome women—and though many have come from there to the gain of other places, there are still not a few remaining. Among the best of them is the present Dean of Norwich, who combines with other good qualities a just appreciation of the value of medical services. In his sermon at the Cathedral on Hospital Sunday, he delivered a eulogy upon the physician and his work of charity among his fellows. This is perhaps not particularly worthy of notice, for we are frequently told on public occasions how good we are, and usually must rest satisfied with this patronizing approval; but the Dean is a practical man and one who believes that the laborer is worthy of his hire, and he told his people in plain words that they must pay their doctors for work done. His remarks concerning doctors' bills, says the *British Medical Journal*, should be widely read, for they deserve the attention of many whose position in the world is undisputed, who stand well with their neighbors, and are looked on as honest men, but nevertheless relegate the payment of their doctors' bills to the dim and distant future. The Dean is reported as having said: "Nor can I, nor shall I, be silent about the wrongs to which scores of medical men are subject. I refer to the startling contrast there is between the inexorable demands which society makes on medical men and the elasticity of the social conscience with respect to their remuneration. I have known cases where men are summoned, at all hours, and at all seasons of the year. Their bills are presented with timidity, if not anxiety, and they are received sometimes with

amazement, sometimes with indignation, and sometimes relegated to oblivion. Nor are cases unknown where the righteous demand for work done is met by calling in another practitioner, he in turn to suffer as his brother did before him. I cannot permit myself to imagine that I address any such wrongdoer here to-day. But if I do, then, in my Master's name, I entreat you to remember that the medical men of this nation are the highest type of their class in the world ; they are entrusted with the secrets of domestic life ; they have all our liabilities, with the special liabilities of their order ; they frequently die as martyrs to science, to suffering, to sympathy, to destitution. . . . Believing this, my plea is that every unpaid medical bill be discharged generously, gratefully, cheerfully, and that whatever account must be deferred in payment, the last to be deferred is the account of him who is the human agent who has brought us into the world, enables us to continue our work in life, and many a time lays down his own in endeavoring to baffle death."

News of the Week.

The Health of the Pope.—The Rome correspondent of *The Lancet* writes that the out-of-door life the Pope leads in the beautiful demense between the Vatican Palace and the Janiculan has told favorably on his health, which, all things considered, was never better than to-day. For one thing, he has no threatening of those fainting fits which, in the spring months especially and during the exigencies of urgent business, were apt to overtake him. With due allowance for the senile anæmía of which he has more than the average octogenarian's share, this result is of very good omen. Dr. Lapponi, physician to His Holiness, in reply to an interrogatory addressed to him, said that if nothing unforeseen happens, the Holy Father's constitution is so sound that he might well attain his hundredth year.

Dr. Giacomo Asiari, of Pesaro, Italy, attained his hundredth year on July 29th, having been born at Forli on that day in 1795. He received his medical diploma from the University of Florence in 1821. In June, 1861, he retired from practice, the town council of Pesaro voting him an annual pension in recognition of his professional and civic virtues.

Anthrax is reported as prevailing in epidemic form among the dairy cattle near St. Louis.

Cycles for Invalids and Doctors.—The possible uses of the cycle, says the *British Medical Journal*, have not yet been dreamt of. The cumbersome Bath chair for invalids is giving place to a light wicker chair mounted as a tricycle driven from behind. In this easy little carriage an invalid can be trundled about the country lanes at the rate of five or six miles an hour, enjoying the breezes and the sunshine and the invigorating pleasure of change of scene at very small expense. Many country doctors have long been accustomed to pay their visits on a tricycle ; but we hear now of a cycle cab used by a metropolitan doctor, which is driven by two youths, one behind and the other in front. By this method fatigue is avoided and the expenses of the stable abolished.

The Heidelberg Ophthalmological Congress has awarded the Graefe Medal to Dr. Theodor Leber, Professor of Ophthalmology in the University of Heidelberg.

The German Emperor has promised a subscription of 10,000 marks ($2,500) toward the cost of erection of a statue to Helmholtz in Berlin.

Railroad Liability for Medical Services.—The liability of railroads for medical services to victims of injuries when attended by physicians not in railroad employ is the subject of very contradictory decisions by the courts. The recent decision of the Kansas Supreme Court in the case of Steelsmith *vs.* the Union Pacific Railroad is in the line of ordinary rules governing contracts. Dr. Steelsmith, of Abilene, Kan., was called by the station-master to attend a brakeman fatally injured in the discharge of his duty, the local surgeon being away. Payment for the services rendered was refused. Dr. Steelsmith then brought suit in the Justice Court, which decided in his favor. The company appealed to the District Court, which reversed the decision of the Justice Court. Dr. Steelsmith appealed to the Kansas Supreme Court, which reversed the decision of the District Court, awarded him the full amount and assessed the costs on the railroad company. The legal principle governing the decision is equitable and has long been law, yet it was contemptuously disregarded by the District Court.—*Medical Standard.*

Surgeons are said to be much in favor of the bicycle because it "helps their specialty." We hear of one doctor at a summer-resort who had twenty cases of bicycle accidents in four weeks. The *Scientific American* gives an explanation of the physics of bicycle accidents which is very impressive. The ability, it says, of a bicycle and rider in rapid motion to do serious damage in a collision with another machine or with a pedestrian is fully appreciated by few wheelmen. A man weighing one hundred and fifty pounds and moving at the rate of ten feet per second (which is only about seven miles per hour) has a momentum of 1,500 pounds, leaving out of the account the weight of the wheel. This is sufficient to upset any pedestrian with terrific force. A collision between two wheels, each with a 150-pound rider, spinning at the moderate speed of seven miles per hour, would result in a smash-up, with a force of 3,000 pounds. In view of these facts, it is no wonder that bicycle accidents are often very serious. The tractive force required to propel a bicycle over a smooth level surface is estimated at 0.01 of the load ; calling the load 150 pounds, a force of a pound and a half would be required to move the wheel forward, and this calls for a pressure on the pedals of six pounds and three-quarters on a wheel geared in the usual manner. When, however, the road is rough, or on an up grade, the case is different. On a grade of 1 in 10, for example, the rider, in addition to the tractive force, actually lifts one-tenth of his weight and that of the machine.

The Cholera.—The disease is supposed to have been brought to the Sandwich Islands from China in the

steamship Belgic, which arrived on August 9th, with over five hundred Chinese immigrants, some already suffering from diarrhœa. Up to August 24th there had been six cases. After that there were none, until the 30th, when nine cases were reported, one a seaman on the United States steamer Bennington. Up to September 8th there were fifty-eight cases with forty-four deaths, all the cases being among the natives and Chinese, except those on the Bennington. Seventeen of these cases, with nine deaths, had occurred since September 5th, so that the disease appears to be increasing. The steamship Rio Janeiro, which arrived at San Francisco on September 16th from China, Japan, and Hawaii, brings consular certificates showing that the disease prevails in Yokohama, Nagasaki, and Honolulu among the ports at which she touched. At Tangier, in Morocco, cholera has been declared epidemic, twelve new cases having been reported on September 16th. A bacterioscopic examination by Spanish medical officers shows the affection to be genuine Asiatic cholera.

The British Association for the Advancement of Science.—The sixty-fifth annual meeting of this association was held at Ipswich, on September 11th, 12th, and 13th. Sir Douglas Galton, the president, while delivering the annual address, which was of unusual length even for such an occasion, fainted.. He soon recovered, but was unable to continue the address, which was finished by one of the members. Dr. Percy Frankland delivered a eulogy on "Pasteur, the Chemist, Physicist, and Biologist." The next meeting of the Association will be held in Liverpool, in 1896, under the presidency of Sir Joseph Lister. It was voted to hold the meeting following that, namely in 1897, in Toronto.

Professional Dignity in Belgium.—A drygoods establishment in Liége, among other inducements to attract custom, advertises to give credit for all purchases, to insure the goods bought against destruction by fire, and to supply free medical service to the purchaser and his family for a length of time proportional to the amount of the purchase. After completing his purchase the customer receives one or more coupons, according to the amount of his expenditure, each one entitling him to a visit from the physician whose name and address are there printed. With cool effrontery *Le Scalpel* calls this a *procédé Américain*, as if Belgium were not a by-word for quackery among the nations of the earth.

Dr. Ellwood Overstreet, of Petrona, Ind., was shot a few days ago by a patient to whom he was about to give a hypodermic injection of morphine. The man, who appears to have been maniacally excited, refused to take the remedy by the mouth and warned the physician not to attempt to give it to him any other way.

The Metric System.—In the forthcoming edition of the British Pharmacopœia the metric system will be introduced side by side with the old weights and measures.

The Index Medicus.—Seventeen additional subscriptions were received by Dr. Billings for the *Index Medicus*, from August 24th to September 7th.

The Chair of Pathology in the Jefferson Medical College of Philadelphia is said to be vacant.

The Police and the Bicyclers.—Paris journals state that the Chief of Police is going to arrest all women promenading the streets, who are wearing the divided skirt. If mounted upon a bicycle the lady is safe, but the moment she gets upon the pavement she is liable to arrest. This sensitiveness of the French mind to the attire of the bicycle lady is almost pathological.

The Practice of Medicine by Druggists.—The French Court has confirmed the sentence of a druggist who was fined 125 francs for practising medicine without a license. The druggist simply prescribed the application of compresses of a two per cent. solution of carbolic acid. Surely our druggists live under a much more liberal *régime* than those of Paris.

The Medical Poet of Finland.—Dr. Elias Loennrot, a country physician of Finland, has been called the "Christopher Columbus of Finnish poetry." Dr. Loennrot has written one or two epic poems, celebrating the early history of the country.

At a Recent Annual Meeting of the Alumni of the Chicago Medical College, the graduates presented to the college three life-sized bronze busts: one of Dr. Hosmer Allen Johnson, one of Dr. William Henry Byford, and the third of Dr. Joseph S. Jewell.

Large Bequests to Massachusetts Institutions.—Under the will of the late Thomas O. H. P. Burnham, who was for many years a dealer in second-hand books, nearly two-thirds of an estate of $602,562 will go to charitable and educational organizations. The Massachusetts General Hospital was made the residuary legatee, and has been paid $263,048. The Home for Aged Men, and Tuft's College will receive $10,000 each; Children's Home, Children's Hospital, Boston Asylum and Farm School, Washington Home, Massachusetts School for Feeble-minded Children, Perkins' Institute for the Blind and Boston Lying-in Hospital, $5,000, each; Boston Dispensary, Asylum for Aged Females, New England Hospital for Women and Children, and Consumptives' Home, $2,000.

The Miscellaneous Uses of Thyroid Feeding.—Dr. Mosse, of Paris, says that in one patient who had entered his hospital for simple jaundice and who also had a psoriasis of long standing, he used the thyroid gland after the usual remedies had failed, and produced a rapid and permanent cure. In a case of goitre of a young girl, the thyroid did no good. Dr. Thiberge, another Paris physician, got no results in psoriasis in three cases, and got very little permanent help in eight others.

Medical Men in Parliament.—In the English House of Parliament there are, altogether, ten medical men. Of these seven are Irishmen, representing nothing, says *The Practitioner*, but the discontents of that political Mrs. Cummidge; two are Scotch; and one only is English. In fact, practically speaking, says our contemporary, the medical profession has only two representatives, Sir Walter Foster and Robert Farquson. When, we would ask, is an Irish doctor not a doctor? The answer is given above.

Clinical Department.

INFECTIOUS ENDOCARDITIS OF THE TRICUSPID VALVE.

By HERBERT UPHAM WILLIAMS, M.D.,

BUFFALO, N. Y.

Edward O'B—— entered the Erie County Hospital December 5, 1894. Service of Dr. Pryor. Aged fifty-six, married, Irish, laborer, family history good, hard drinker, and hard worker. On entering he had cough, rusty sputum, cyanosis, dyspnœa. Respiration, 50; pulse, 110; temperature, 103° F. Examination showed expansion of chest diminished, tactile fremitus increased universally, sibilant râles heard over both lungs, but most marked over upper lobe of right, increased dulness over whole chest, but most marked posteriorly. Diagnosis of lobar pneumonia of right lung and œdema of the lungs.

December 15th.—Bronchial breathing heard posteriorly on both sides, subcrepitant râles heard over upper lobe and anterior aspect of right lung, with increased dulness over the same region. About this date the patient began to vomit, and to have several chills daily, accompanied by high rise of temperature, and followed by sweating.

December 26th.—The chills have continued one or more times daily; the patient is said to have as many as two in one hour; the chills have been accompanied by rise of temperature from 103° to 105° F., followed by copious sweating and fall of temperature. The patient has continued to vomit thin greenish material; 500 c.c. to 650 c.c. of urine passed in twenty-four hours, containing 21.5 gm. of urea, abundant albumin, and epithelial cells, but no casts.

December 28th.—Showed no abatement of the frequency of the chills, temperature usually reaching 105° F. after a chill. Throughout, the examination of the heart was unsatisfactory on account of the noisy breathing; therefore, although malignant endocarditis had been suspected, no confirmation could be obtained from physical examination. The possibility of a central abscess of the lung existing was also considered, and for diagnostic purposes exploration was made with the needle on both sides, opposite the angle of the scapula, but with negative results.

The patient was intelligent, and conscious through the entire course of his disease. The chills continued without interruption until the day of his death, January 7, 1895. On the day before his death the temperature reached 106° F.

Autopsy, January 8th, about twenty-four hours after death. Usual post-mortem discoloration of dependent parts; rigor mortis firm; subcutaneous fat abundant. Both lungs adherent in spots over all surfaces, but not firmly; left lung congested posteriorly, on section exuding bloody froth; upper lobe solid, red, outlines of lobules well marked, exuding bloody and purulent fluid; right lung firm throughout, the upper lobe being grayish in color, mottled with black, quantities of pus issuing from bronchial tubes; lower and middle lobes less completely solidified, and containing some air, very dark red color, bronchial tubes exuding pus, firm thrombi of pink color found in several of the smaller branches of the pulmonary vein in the lower lobe. Pericardial cavity contained about thirty cubic centimetres of serum; position of heart normal, heart large, flabby, ventricles empty. Spleen large, soft; pulp grayish-red in color. Kidneys, capsules stripped off easily; on section general appearance pale, cortex grayish-white, with distinct reddish striations; medulla reddish-pink; urinary bladder normal. Liver large, very flabby, light reddish-brown, centre of lobule red, outer part gray, cut surface greasy. Mucous membranes of stomach, small intestine, cæcum, vermiform appendix, and large intestine all normal. Brain not examined.

Diagnosis: Lobar-pneumonia of upper lobe left lung and entire right lung, acute splenitis, parenchymatous degeneration of liver and kidneys.

Most interesting was the heart. Mitral orifice admitted two fingers, mitral valve presenting no unusual appearances except a small reddish-brown discoloration, not elevated, on the posterior segment; aortic valve normal; a few small atheromatous patches in aorta; muscle of ventricle pale, flabby, greatest thickness of left, 13 mm., of right, 5 mm.; the pulmonary artery contained a yellowish fibrinous clot; pulmonary valve normal. Of the tricuspid valve the left segment was much thickened, and its upper surface rough, and covered with a deposit of fibrin from the free margin to within 10 or 15 mm. of the attached edge; the portion attached appeared normal; the anterior segment exhibited two round areas, close to the free margin, each about five millimetres in diameter, each the seat of thickening and accumulation of fibrin; removal of the fibrin on these spots showed the tissues of the valve to be eroded; the posterior segment appeared normal.

Both coronary arteries and their branches were examined without finding any thrombosis, embolism, or other abnormality.

The heart was placed in alcohol about an hour after its removal; after hardening, and embedding in celloidin, numerous thin sections were made. The left-hand and most diseased segment of the tricuspid valve examined histologically was found healthy at its basal part, becoming, as the thickened free edge was approached, the seat of infiltration with small, polynuclear, round cells on the auricular surface in the subendocardial layer, and extending, farther on, through all the tissues of the valve. The auricular aspect of the valve was then found converted into a thick homogeneous, hyaline layer, containing very few nuclei, but surrounded by the small-cell infiltration above mentioned, whose nuclei appeared densely packed in this situation, fading away gradually into the relatively healthy parts of the valve, often arranged in strings. The nuclei of these cells frequently showed fragmentation. There was also multiplication of nuclei close to the ventricular surface. Masses of fibrin were observed attached to the hyaline necrotic tissue. Near the margin of the valve the increase in thickness became very great, and the entire substance of the valve was converted into homogeneous hyaline material, rarely exhibiting nuclei. With the Weigert fibrin stain strings and irregular masses of fibrin were demonstrated through the hyaline valve tissue and attached to its surface; fields could be seen pervaded by a delicate fibrin net-work. Bacteria were found in the hyaline valve tissue, and just below its surface, loosely or in clumps in what appeared to be lymph spaces, within the masses of fibrin, and in the area of cell-infiltration. They were most abundant in the first-named locality. They stained with watery solutions of the aniline dyes, by Gram's method, and by the Weigert fibrin stain, best by the last. Morphologically they varied from round, through oval forms, to bacilli with rounded ends, often club-shaped and staining unequally. The oval type prevailed. Much irregularity in size was noted. The smaller cocci measured 4μ to 6μ; the larger bacilli attained a length of 3μ. Many times the cocci and oval forms were observed in pairs. No capsule could be demonstrated.

Similar bacteria were found in sections made from one of the small round ulcers mentioned as occurring on the right-hand segment of the valve, which no doubt was infected from the left-hand segment. Search through sections of the base and attachment of the valve and the adjacent muscle, and of the muscle of both ventricles, and of the coronary artery failed to demonstrate any bacteria.

The muscle cells showed their transverse striations

distinctly ; their nuclei stained well for the most part, but at times faintly ; the pigment granules about the nuclei were well developed. No fat could be seen in the muscle cells, which in any case would not have been expected, as the tissues were hardened in alcohol and embedded in celloidin.

The clinical history indicated that the pneumonia preceded the endocarditis. During more than four weeks no progress was made toward resolution in the solidified lobes. The endocarditis dated very likely from the chills, which commenced ten days after the patient came under observation.

The case was studied with the idea that infection might have proceeded from septic emboli carried from the lung into the heart by way of the coronary artery. But the location of the inflammatory process along the margin of the tricuspid valve, the absence of embolism in the branches of the coronary artery, the failure to find bacteria at the base of the valve or in capillaries in other parts of the heart, all make this explanation appear improbable.

It is extremely to be regretted that the circumstances of the autopsy did not permit of the use of culture methods to determine the nature of the bacteria, which were beyond a doubt the cause of this endocarditis. The morphological differences noted in them are compatible with their having been all of one species ; but it is not impossible that the case was one of mixed infection. The source of infection was in all probability in the lungs.

A CASE OF SUCCESSFUL TREATMENT OF ENURESIS NOCTURNA BY THE TEST OPERATION.

By GUSTAVUS BLECH, M.D.,

DETROIT, MICH.

The patient, a girl, fourteen years of age, servant, suffered quite a long time from enuresis nocturna. She was treated by different physicians with drogues, massage, electricity, etc., without any improvement of her disagreeable condition. Patient is rather stout for her age, well developed, and menstruated regularly for the last six months. Family history good ; no similar case on record. Inspection reveals nothing abnormal, with the exception that she cannot retain her urine for a longer period. This fact led me to believe that there existed a natural relaxation of the urethral walls. Having noticed in the *Frauenarzt* for May, 1895, a description of a new operation for incontinentia urinæ by test, I decided to undertake it in this case, as an energetic measure was indicated, the girl being obliged to earn her own living, and unable to find constant employment on account of this trouble.

The test operation consists in vertical incisions at both sides of the meatus urinarius, transforming the vertical wound in an horizontal by passing sutures through the upper and lower end of the incision, and bringing the margins into exact approximation. A few more fine stitches close the figure-of-eight opening. By this procedure the tissues around the urethra become thickened on both sides, and the traction exercises also pressure upon the urethra. The resistance of the canal is increased and greater force is necessary to expel the urine. The operation was almost painless after an injection of one-half drachm of a five per cent. solution of hydrochlorate of cocaine in each side. The bleeding ceased after suturing. No catheter was used. The parts were protected against irritation from the urine by application of borated vaseline. Healing took place per primam intentionem. After the operation the patient could pass her urine only in a fine stream, but after complete healing and consequently strengthening of the sphincter, the act is done normally. She can retain the urine over night, or awakens in due time to avoid incontinence.

ANGIOMA CAVERNOSUM OF THE SPLEEN.

By M. D. HOGE, Jr., M.D.,

PROFESSOR OF HISTOLOGY AND PATHOLOGY UNIVERSITY COLLEGE OF MEDICINE, RICHMOND, VA.

Angiomata, from their structure and formation, are divided into capillary and cavernous forms. In the former there is a distinct formation of blood-vessels produced by the excavation of solid nucleated protoplasmic cells, which gradually become converted into tubes. These tubes, or rudimentary capillaries, are always connected with some previously existing blood-vessels. Such growths form the simpler kind of congenital nævus vasculosus. These nearly always occur in the skin, sometimes in the subcutaneous tissue or mucous surfaces, very rarely in internal organs.

In angioma cavernosum the capillary system is lost, and the blood is contained in a number of freely intercommunicating spaces which resemble the corpora cavernosa of the penis. These occur more frequently in the subcutaneous tissues, in the orbit, pharynx, nose, and internal organs. They often pulsate, and are connected by wide openings with arteries and veins, especially the latter. The liver is almost always the location in which this form of tumor is found, and it is on account of its extreme rarity of occurrence in the spleen the present case is reported.

Mrs. M——, aged forty-five, was admitted into St. Luke's Home, May 2, 1895, complaining of a gradual loss of flesh from 144 to 129 pounds, and lately a rather rapidly growing tumor on the left side. She had been in perfect health up to ten years ago, when she suffered from alternating attacks of constipation and diarrhœa. She is the mother of thirteen children, three of which were stillborn. Four years ago, after the birth of her last child, she noticed the swelling on the left side, which caused her much anxiety on account of its rapid and mysterious growth ; it was never actually painful, but constant brooding over it reduced her much, both in flesh and spirits. She has never had malaria, and has been singularly exempt from all kinds of sickness.

Dr. Hunter McGuire, in performing the operation, made a median incision, which at once disclosed a dark, soft, highly vascular tumor, extending well down toward the left ovary. On looking for the attachment, it could be followed up to the spleen ; it was at once removed, and the bleeding stump secured. When sent for examination it was found to be kidney-shaped and measured eight inches long, five inches wide, and an inch and a half thick. Small pieces were at once fixed in formal and absolute alcohol, stained in various ways and mounted in balsam. Under the microscope the entire spleenic structure had disappeared, and in its place large cavernous openings were seen, freely communicating with each other and around the outer edge indications of a more or less distinct fibrous capsule.

On account of the great rarity of this form of tumor invading the spleen, and the perfect and uninterrupted recovery of the patient, the case has been reported.

Pieces of tissue were sent to Dr. James E. Reeves, of Chattanooga, Tenn., who confirmed the diagnosis of cavernous angioma of the spleen.

A letter from the patient, dated August 3, 1895, states that she is now in perfect health.

A Stroke of Genius.—There is a woman in an Ohio town whose ability as an advertiser demands a wider field for its exercise. She is an "electric physician," and recently appeared before the local Board of Health with a complaint against one of her neighbors who kept several cows. She was so full of electricity and magnetism, she said, that she drew the flies in swarms from the cows, and she wanted the Board to abolish either the flies, the cows, or the owner of the latter, as she said she could not possibly stand it any longer.

Society Reports.

THE BRITISH MEDICAL ASSOCIATION.

Sixty-third Annual Meeting, held in London, July 30 and 31, and August 1 and 2, 1895.

(Specially Reported for the MEDICAL RECORD.)

SECTION ON PHARMACOLOGY AND THERAPEUTICS.

FIRST DAY, WEDNESDAY, JULY 31ST.

Anarcotine in Malarial Fever.—SIR WILLIAM ROBERTS took, as the subject of his presidential address, "Anarcotine, a Neglected Alkaloid of Opium." During his visit in India as a member of the Opium Commission his attention had been called to the employment of this alkaloid in the treatment of malarial fevers. Anarcotine was brought into prominent notice in India about fifty years ago. At that time quinine became very scarce and dear, and the Indian medical authorities had to cast about for some cheaper and more abundant substitute. Now, opium had long been held in high repute among the natives of India as a remedy and protective against malarial fevers; and habitual opium-eaters were said to enjoy a remarkable immunity from malarial infection. Attention was therefore directed to anarcotine, which is the most abundant alkaloid of Bengal opium, and trials were made of its curative power in malarial fevers. The results of these trials induced the Indian authorities to institute further experiments, and these proving favorable, they caused anarcotine to be prepared in quantity and distributed to the medical depôts throughout British India.

In 1857–59 Dr. Palmer treated at Ghazipur 546 cases of malarial fever with anarcotine, in doses ranging from one to three grains. Of these 541 were cured and only 5 died. In addition to these 546 officially reported cases he treated with anarcotine a large number of other cases of malarial fever, amounting in all to little short of 1,000 cases. Summing up his general experience, he states that in seventy per cent. the fever was arrested at the second paroxysm after the medicine was administered; in twenty per cent. the arrest was equally sure, but was not quite so quick; and in ten per cent. the medicine did not appear to have any curative effect. He further remarks that there are cases where anarcotine is decidedly more efficacious than quinine, namely, where there is an intolerance of quinine, and where quinine has been given without any effect for a long time.

Dr. Garden succeeded Dr. Palmer in civil charge of the Ghazipur Station in 1859; and at that time a severe outbreak of intermittent fever, of quotidian and tertian type, had to be dealt with. Taking advantage of the opportunity he subjected anarcotine to an extensive trial. He treated altogether 684 cases, and gives details of 194. Of these 194 cases 187 were rapidly cured by anarcotine. It only failed in 7 cases, or 3.6 per cent. It, moreover, cured some cases where quinine had failed. The doses he employed ranged from one and a half to three grains. Dr. Palmer and Dr. Garden perceived a distinction between quinine and anarcotine, and recognized that there were cases of malarial fever which resisted quinine but yielded to anarcotine. Both observers also noted that in a certain percentage of the cases anarcotine proved wholly ineffective. These discrepancies are probably to be explained by the facts brought to light in recent researches on the infective organisms of paludal fevers. It has been shown that these organisms are of more than one kind, and that each kind corresponds to a particular type of malarial fever. There seems to be valid evidences that in anarcotine we possess a second antiperiodic of great power analogous to, but not identical with, quinine. The speaker emphasized the desirability of subjecting anarcotine to a fresh examination, with a view of ascertaining its value, as compared with quinine, in the different types of malarial infection, and in cases where quinine has proved ineffective. Anarcotine was originally named "Narcotine" by its discoverer, Derosne, and this is the name by which it is still generally known. This designation is, however, wholly inappropriate and misleading, as, when pure, it is quite devoid of narcotic properties.

A Discussion on Serotherapy was opened by DR. E. KLEIN with a paper upon the "Nature of Antitoxin." One of the oldest deductions that have been made as to infectious diseases was that a first attack confers a certain immunity against a second. Modern pathology distinguishes, as acquired immunity, the condition of insusceptibility after a first attack from natural insusceptibility observed in certain individuals or in certain species of animals against any one kind of infectious disorders.

Natural immunity is altogether different from acquired immunity, the former being probably dependent upon some peculiarity of cells or tissues: the latter to the presence of chemical substances in the blood, which were termed anti-bodies. The methods of production of antitoxin by injection of gradually increasing doses of the toxins or of the toxins plus living bacilli were then briefly described. The antitoxins had a very great power of neutralizing the toxins, but much larger doses had to be employed if living bacilli were present in addition. Hence the antitoxic substance and the substance immunizing against the living bacilli seemed to be distinct, and, in fact, it could be shown experimentally that they were not formed simultaneously or to the same degree. The antitoxic substance was perhaps a ferment, and in the future two classes of animals might be kept, one class immunized against the toxins, and furnishing antitoxin for the treatment of diphtheria, another class immunized against the living bacilli, and furnishing a serum which might be used for preventive inoculation. Experimentally, the value of antitoxin was as firmly established as that of any known drug.

DR. J. W. WASHBOURN said that the discovery of serum therapeutics marks a distinct epoch in the history of medicine. During recent years rapid strides have been made in surgical therapeutics owing to the introduction of methods of treating wounds which are based upon sound scientific principles. In medicine our knowledge of the etiology and pathology of disease has been greatly enriched during recent years by the study of physiology and bacteriology, but medical therapeutics, with the exception of the progress due to improved methods of diagnosis, has, until within the last year, remained almost at a standstill.

The progress of bacterial therapeutics has been slow, and it received a set-back in the failure of tuberculin. But that failure was due to the fact that the experimental proof of its value rested upon insufficient evidence. The application of the treatment to the human subject was attempted before it had been proved to be efficacious in the case of animals. The principle of serum therapeutics rests upon an entirely different basis. Careful and accurate experiments have shown that the blood-serum of highly immunized animals possesses remarkable therapeutic properties. In regard to diphtheria antitoxin, the remedy had been thoroughly and satisfactorily tested before it was applied to the treatment of the disease in man. With regard to tetanus antitoxin, the results seem as yet to be somewhat disappointing, but the cases treated have been too few to warrant any definite conclusions. There are two methods by which the value of diphtheria antitoxin can be gauged—the clinical and the statistical; and a large number of cases are now available for this. In regard to the statistical method, it is most important that the age of the patients should be mentioned, for whereas

for children under five years the mortality is 49 09 per cent., for persons over fifteen years the mortality is only 4 6 per cent. The varying severity of different epidemics is also a factor which must not be neglected. The position of the membrane, whether faucial or involving the larynx, is another important factor. Excluding all sources of fallacy, we now have records of over three thousand cases treated with antitoxin, and statistics show a diminished mortality, in some instances one-half that which existed in pre-antitoxin days. This was the case in Paris, where at the same time at the Trousseau Hospital under the old treatment the mortality remained up to the average, and also in Berlin, where there was a great diminution of mortality when the antitoxin was used, a rise when the supply of the remedy failed, followed at once by a decline on the resumption of the use of the remedy. Statistics, therefore, definitely prove the advantage of the antitoxin treatment. The speaker then dwelt in some detail upon the effects of the remedy as manifested clinically. The exudation clears off more rapidly, obviating in many cases the necessity for tracheotomy. The temperature when high is lowered, the pulse becomes slower and more regular. No deleterious effects upon the kidneys could be ascribed to the remedy.

As to the effect of the antitoxin treatment upon the occurrence of paralysis more extended observations are required before we can arrive at a conclusion. In this connection, however, we must not forget that the more severe the attack of diphtheria the more likely is paralysis to supervene. Many fatal cases would probably have developed paralysis had they recovered. Consequently when the mortality is lowered by treatment the actual number of cases of paralysis may increase through this cause alone.

When the false membrane has been invaded by pyogenic bacteria the action of the antitoxin may be interfered with. Slight complications, such as rashes, pyrexia, and joint pains, sometimes attend the use of the remedy, but these are of a transient character and retard recovery simply. The rashes are of an erythematous or urticarial nature, and the joint pains proceed usually from the structures around the joint, although actual effusion may occur. The speaker emphasized the importance of antiseptic precautions. The syringe should be one that can be boiled easily. The dose should vary according to the age of the patient and the severity of the disease. As regards the prophylactic use of the serum, the protection did not last long, and it would only be exceptionally indicated. In conclusion, the possibilities of serum therapeutics were touched upon as applied to bacterial diseases such as erysipelas, pneumonia, puerperal fever, and the like.

Dr. Charteris spoke of the cases of diphtheria he had seen treated with antitoxin. There seemed to be no doubt about its efficacy; the membrane ceased to spread, the pulse became fuller and stronger, and the whole aspect of the patient improved. He had experimented with the various makes of antitoxin in the market and had observed no injurious effects from any of them.

Dr. R. T. Hewlett confined his remarks to tetanus antitoxin. He first gave a brief outline of the methods employed by Behring, Roux and Vaillard, and himself, in obtaining tetanus antitoxin. He pointed out that the antitoxin issued by Tizzoni differed from the others in that it was obtained by precipitation of the serum by means of alcohol; in the other cases the serum was issued either in the usual liquid form, or was reduced to a solid by being dried *in vacuo* over sulphuric acid. All these antitoxins possessed a very high immunizing power, which should never be less than 1 to 1,000,000. The mortality of tetanus under the old methods of treatment was about seventy-five per cent. The speaker had collected statistics of 61 cases treated with antitoxin, and of these 22, or thirty-six per cent., died. It is probable that these figures are somewhat too favorable, but after making all allowances, the antitoxin treatment of tetanus is undoubtedly an advance.

Dr. Nestor Tirard referred to the results of the antitoxin treatment of diphtheria at the Evelina Hospital. The pulse gained strength, and in some cases diminished in rate; the temperature either fell or remained the same—in no case did it rise; the nervous system gained in tone, and the membrane speedily diminished and did not form again. With regard to ill-effects, it was found that albumin was found in the urine in many cases, but this was also often noticed before the antitoxin had been used at all, and it was unaccompanied by any symptoms referable to interference with renal function. A rash had been noted in three cases; it was always of the nature of an urticaria, and gave no trouble. Post-diphtheritic paralysis had not been observed. While it was possible that the greatly diminished death-rate might be due to an unusually favorable epidemic, yet the cases treated had been very severe in their clinical features.

Dr. W. Gayton was not much in favor of the antitoxin treatment of diphtheria. The reduction in the death rate is slight (not more than five per cent.), and may well be due to a mild character of the disease at the present time. The number of cases complicated with nephritis is much greater, and paralysis is more common. The experience of himself and his colleagues at the Northwestern Fever Hospital might be summed up thus: Those cases that under the old treatment would probably have died still were fatal under the new. Those which might get better recovered in about the same proportion, while the mild cases improved no more rapidly—indeed rather the contrary, considering the frequency of the incidence of rashes, than those without it.

Dr. Foord Caiger had employed antitoxin in two hundred and thirty cases of diphtheria, and was impressed with the value of the remedy. There were fewer cases with heart failure, but more of paralysis—a fact that could readily be explained by the greater number of severe cases that recovered. The membrane, which before the use of antitoxin was adherent, on an average, 4.6 days, now fell off in 2.6 days. In the nasal form the acrid discharge was soon checked and the patients rendered more comfortable. In laryngeal cases the benefits were most marked; both the membrane and swelling soon disappeared, and the number of cases requiring tracheotomy was reduced from seventy per cent. to forty-three per cent. The mortality was also lessened, and in cases that eventually terminated fatally the duration of life was extended—lengthened an average of very nearly three days. The speaker gave much larger doses than were customary. He began with 50 c.c., and gave sometimes as much as 180 c.c. in the first three days. He believed that the results were much better if large doses were given.

Dr. Fraser discussed the modes of testing the strength of antitoxin, and said he considered them faulty, as tending to convey an exaggerated idea of the strength of the remedy. Instead of the antitoxin being given before or at the same time with the toxin, the test should be made to conform more nearly to what occurs in practice by administering the remedy some time after the toxin has been taken.

Mr. Bokenham said that the bulk of the fluid to be administered was a serious difficulty in private practice; cases were known to him in which the parents had withdrawn a consent previously given when they saw the size of the syringe to be used. He thought he had overcome this objection in a fairly satisfactory manner. By a process of drying, combined or not with previous concentration at a low temperature *in vacuo*, he had succeeded in reducing the serum to a condition of thin golden scales; 100 c.c. yield on an average between 10 and 11 gm. of dry scales. These are readily soluble in about two and a half to three times their weight of water, and the activity of the

solution thus made is almost identical with that of the original serum. He had heard of no ill-effects following its use; it keeps perfectly, and may be used with a comparatively small syringe.

Dr. Klein, in closing the discussion, spoke approvingly of the use of dried serum, and he believed it would be found less likely to produce a rash than the ordinary form.

Dr. Washbourn said that the cases upon which Dr. Gaynor based his unfavorable opinion were altogether too few to have any particular value one way or the other, yet what little they did show was in favor of the new remedy, since the mortality had been reduced five per cent. The report was very unsatisfactory, in that nothing definite was said as to the dose or the mode of administration of the antitoxin.

Antivenene in Snake-poisoning.—Dr. T. R. Fraser read a paper upon the induction of artificial immunity to snake-bites. It has long been suggested that the feats of snake-charmers were rendered possible through the production of artificial immunity. If this be the explanation, the protection must have been obtained, in most cases, at least, by the introduction of the venom into the stomach. It is generally asserted that snake-venom is innocuous when taken into the stomach, yet it does not necessarily follow that it is incapable of producing protection when swallowed. To test this, Dr. Fraser experimented upon cats and white rats, and found that immunity could be secured by the stomach administration of the venom. The blood-serum of serpents, as shown by some of the speaker's experiments, also contains a substance which possesses antidotal properties against their own venom as well as against that of other species. This antitoxic substance he called antivenene. The antidotal action of antivenene seems to be rather of the nature of a chemical reaction than of a physiological antidote. With regard to the administration of antivenene, several successive doses would appear to be more effectual than one large one. It should be injected at the seat of the bite, before the ligature, if applied round the limb, had been removed, and before excision. It will probably be found that 20 c.c. is sufficient for the initial dose. Dr. Fraser exhibited two preparations of antivenene, one in the usual liquid form of remedies used in serotherapy, the other the blood-serum dried *in vacuo* over sulphuric acid. The dry antivenene is readily soluble in water, and retains unimpaired the original antidotal power of the liquid preparation.

Dr. Stokvis, of Amsterdam, said that he was much interested in the possible effects of the epidermic application of antivenene. He stated that in the Dutch colonies it is customary for the snake-catchers to prepare themselves before starting by rubbing all over their skin a powder made from the dried heads of snakes, with their poison-glands. As a result of this precaution they either are not bitten, or they are rendered immune against the effects of bites.

Dr. Fraser said that he had not tried epidermal application of antivenene, but as immunity could be produced by absorption through the epithelial lining of the stomach it was quite possible that inunction would act similarly. It was worthy of trial.

Second Day, Thursday, August 1st.

Revision of the Pharmacopœia.—The second session of this Section was taken up almost entirely with a discussion concerning the revision of the British Pharmacopœia—what articles should be dropped, what new remedies admitted, whether the new forms, such as tabloids, granules, etc., should be included; whether the details of the making of poultices should find a place, etc. The chair during the discussion was occupied by Dr. Lauder Brunton.

The discussion was opened by Dr. Leech, of Manchester, who, as a member of the General Medical Council, was desirous of learning the views of general practitioners in regard to the changes to be made in the next revision.

Drs. Carter, Stockman, Fraser, and others took part in the discussion.

Drs. Harley and Surveyor then presented a communication on the "Action of Beta-naphthol and Bismuth Subnitrate as Intestinal Antiseptics." This was followed by a paper by Dr. C. D. F. Phillips on the "Pharmacological Action of Berberine."

Third Day, Friday, August 2d.

Therapeutic Uses of Mineral Waters.—The discussion was opened by Dr. Fortescue Fox, who read a paper on "Strathpeffer." These are sulphur waters, and if continued for too long a period were liable to cause anæmia. They are contra-indicated also in acute congestive or inflammatory states of the abdominal viscera, in tuberculosis, acute rheumatism, albuminuria, and uncompensated valvular lesions. They are indicated in the chronic congestions and stases, commonly occurring in people of sedentary habits in later middle life. The speaker was persuaded that the waters were the main factor in the good effects of treatment at resorts of this nature, for the change of air, scene, diet, and surroundings were wholly insufficient to account for the great benefit received in so many cases of chronic disease.

Dr. S. Hyde read a paper on the "Waters of Buxton." There is quite a variety of waters found at, and near, Buxton—saline, sulphur, and ferruginous. Subacute rheumatism was often greatly benefited, although at first the treatment usually caused a return of the acute symptoms; these are of short duration, however, and rapid progress toward recovery follows, a large number of patients being completely cured. In acute gout the internal use of the waters is alone indicated, but in chronic gout the use of baths in addition is useful. In rheumatoid arthritis the combined internal and external treatment, together with massage, gives satisfactory results. Massage is a valuable adjunct in many conditions, but electricity is not particularly beneficial. Other diseases benefited by the waters and methods of treatment in use at Buxton are lumbago, peripheral neuritis, and various skin affections dependent upon gout.

Natural Versus Artificial Waters.—The speaker then referred to the fact, which was one of common observation by all who had had to do with hydrotherapy, that, however closely an artificial water, prepared synthetically, resembled a natural one, it was, nevertheless, lacking in some peculiar property which gave the character to the natural water and rendered it, therapeutically, more efficient. He was at one with the previous speaker in holding that the conditions of change of life and surroundings accompanying treatment at a spa were not sufficient to explain the benefits received.

Dr. A. S. Myrtle said there certainly was some property in natural springs which was lacking in artificial waters, however closely they resembled the natural. He referred briefly to the properties of the Harrowgate waters, and described the plan of treatment pursued by himself. He considered that strict dieting was unnecessary while undergoing the treatment; patients might have anything in reason, food and drink, provided it did not disagree and was taken in moderation. He was in the habit of recommending for breakfast "anything you like, but not too much of it," and just the same for lunch and for dinner. The sulphur waters at Harrogate were the only ones used externally, the sulphuretted hydrogen contained in them being sedative in nervous conditions and in affections of the gastric and bronchial mucous membranes. The other waters were stimulant, diuretic, and tonic. In chronic diseases of the heart the waters were very useful, but should be employed with great care.

Mr. W. Tomlins read a paper on the "Brine Baths of Droitwich." After referring to the large amount of saline constituents which these waters contain, the cases suitable for the treatment were discussed. Attention was also drawn to the attractiveness of the scenery and to the favorable climatic conditions of Droitwich.

Dr. Parsons referred to the value of the spa treatment in diabetes and other diseases.

Dr. Cuffe and others also took part in the discussion.

Loretin.—Dr. Herbert Snow read a paper on this organic iodine compound discovered by Claus, of Freiburg, which is possessed of aseptic properties. It is a yellow, crystalline powder, but slightly soluble in water, and forming emulsions with ether, oil, and collodion. It forms neutral salts with alkalies, which are freely soluble in water. Loretin is odorless and non-poisonous, and is, Dr. Snow said, superior in germicidal power to some of the preparations now in favor with surgeons. It is also a good deodorant, destroying the fœtor of sloughing cancerous sores. Dusted into deep wounds it prevents suppuration, and no bad symptoms had been observed after its use. Applied to the skin or to a granulating sore it is perfectly unirritating.

Guaiacol by Hypodermic Injection.—Dr. F. R. Walters read a paper on the "Subcutaneous Use of Guaiacol." When injected under the skin guaiacol is found to be very irritating, and producing sloughing, but when injected into the muscular tissue the irritating properties are less marked, and very considerable doses may be administered without causing constitutional disturbance.

Yeast Fungi in Tuberculosis.—Dr. de Backer, of Paris, read a paper on the "Treatment of Tuberculosis by Living Ferments." Yeast fungi are made use of and are injected in the living state subcutaneously. The speaker believed that the beneficial therapeutic action of these living ferments, an action which he had now been observing for a considerable time, and which he regarded as little less than marvellous, was to be explained on the theory of phagocytosis.

SECTION ON PATHOLOGY.

First Day, Wednesday, July 31st.

The Process of Repair.—Dr. Samuel Wilks, Chairman of the Section, took this as the subject of the annual address. All about us, he said, change is ever going on; and not only in the world around us, but also in the entire universe, as far as we can learn by the evidence furnished by the telescope and the spectroscope, this same endless succession of growth and decay goes on. Just as the body grows and decays, as a whole, so do its several parts. We may see the two processes of production and destruction going on in the tissues whenever these are subjected to any special stimulus, such as injury or other morbid influence. In speaking of any unnatural condition in the body, we commonly employ the term "morbid," but this is not strictly correct, for only a portion of what is found is really pathological, the rest being the result of a true physiological process. When employing the terms "morbid" or "disease," we do not recognize, as we should, the reparative process that goes hand in hand with the destructive one. With regard to injuries, we seldom have any difficulty in recognizing this reparative action, and in many cases of internal disease also we can readily distinguish the physiological from the pathological. In valvular heart disease, for example, we know that the hypertrophied cavities are the manifestation of a conservative process; and, in like manner, hypertrophy of other hollow viscera is the attempt of nature to overcome obstruction, and is truly conservative and not pathological. There are, however, other more complex states, in which it is difficult to distinguish clearly between pathological and physiological changes. It is possible that the two processes are more intimately associated than we have hitherto believed, and that a mutual relation of a chemical or electrical nature may exist between them. Thus it has been shown that if one electrode is placed upon an ulcer the latter will heal rapidly, while a sore is being produced at the point of application of the other electrode. The two processes are also seen going on before the eye in almost any ulcer, for along with the destruction we see, during the process of granulation and secretion, that new material is being formed. One reason why this double process is so often overlooked is, doubtless, owing to the fact that the reparative material is not equal in organization and similar in structure to the original tissue which it replaces. The complex parenchymatous structures are not renewed, after injury, as are the simpler ones of bone or connective tissue; we do, however, occasionally see true regeneration of glandular or nerve tissue. Still this is true repair, even if imperfect and partial, and we have been wrong in calling the process morbid, instead of reparative. This distinction is a useful one in the matter of prognosis and treatment, as well as of a purely pathological interest. The speaker illustrated his meaning by several examples. As regards phthisis, he said, nothing was more common than an error in prognosis, and this simply because there has been a confusion in the mind of the profession between the constructive and destructive changes present in the lungs. In fact, the very signs which are the strongest evidence of a beginning reparative process are regarded by many as the unmistakable signs of disease. He recognizes the existence of a cavity, and at once condemns his patient, forgetting that the physical signs, dull tympanitic note, pectoriloquy, sinking in of the chest-walls, and absence of vibration all point to the presence of a cavity with hard walls, the result of a reparative action following the destructive process. The destroyed portion has been walled off from the healthy part of the lung by this fibrous barrier, which the examiner has looked upon as a sign of disease rather than of a protection against further spread of the disease. Unfortunately, it is not alone the tyro who make this deplorable mistake, for the speaker had often had occasion to note the surprise of old practitioners on seeing their former phthisical patients alive after they had condemned them to speedy death.

This case of phthisis is, perhaps, the commonest example, where the constructive and destructive processes have not been sufficiently distinguished; but the same may be seen in cirrhosis of the liver. This organ may be observed during life to be first enlarged and then become nodulated and shrunken; among other signs of the disease which the text-books describe is an enlargement of the veins on the surface of the abdomen. These were thought at one time to be due to some pressure on the vena cava, but this is really not the case, and the appearance is now shown to be due to an enlargement of the epigastric vein in connection with the opening up of the old umbilical vein, which often becomes as large as a goose-quill. Through this the portal blood flows and finds a free passage into the vena cava and systemic circulation. The patient in this way is relieved from an engorgement of the portal system and from the consequent dropsy. This enlargement of the veins is, therefore, a sign of a reparative character. And probably this is not all, for when the cirrhotic organ is examined carefully and microscopically we find that, although the nodules are composed mainly of atrophied hepatic tissue, there has also been an attempt to replace it by a new formation of cells and vessels. New blood-vessels may be seen and apparently new ducts, as well as cell growth. Now, although these new elements are not perfect enough to take on the function of the liver, there can be little doubt that they do relieve the circulation in a disabled organ.

There are other cases in which the two processes of

construction and destruction are even more closely interwoven, so that it is often impossible to distinguish between them and to assign the right place to each. We should study these with greater care and more intelligently, for the discovery of the several influences exerted in the production of each is a matter of great practical importance. A consideration of them also shows that pathology is governed by the same laws as those which exist elsewhere throughout the realm of Nature, and it therefore must take its place on an equivalent footing with the other sciences.

The Mosquito as the Intermediate Host of the Malarial Parasite.—Dr. Patrick Manson then read a paper entitled "Some Facts in the Life-History of the Malaria Parasite," in which he advanced the theory that the micro-organism was conveyed to man by means of the mosquito. He began by describing the forms of the parasite seen in the blood of malarious patients, and showed how these varied in their appearances according to the stage of the disease during which they were obtained. The flagellate forms, he said, are only developed outside the body and never within the circulation. In their earliest stages they are merely masses of pigmented granular protoplasm, which can be seen to thrust out the characteristic flagellæ. These separate themselves later from the parent cell and play an important part in the development of the micro-organism after they have escaped from the body. The intra-corpuscular elements are destined to carry on the life of the parasite within the body, whereas the flagellate forms maintain the continuity of the species outside the body. But it has been asked, how the flagellate forms escape from the circulation? In reply to this the speaker referred to the researches of Surgeon-Major Ross, of Secunderabad, which suggested the probability that the mosquito was an intermediate host of the parasite. This observer had found that the parasites resisted destruction in the stomach of the mosquito, and he had also observed that they occurred much more frequently in the flagellate form in the blood of this insect than in blood drawn from the finger of a patient with malaria. The development of the plasmodium in this intermediate host is also evidenced by the fact that the crescent forms all become spheres. Dr. Manson then quoted an instance of a man who by accident had swallowed the contents of a bottle containing malarious mosquitoes, and who, although he had never had the disease nor had been exposed to it, yet developed malaria in eleven days. The disease is apparently not communicated directly to man by the insect, but it is probable that the parasites are added to water or soil on the death of the mosquito, and by that means are carried into the human body. Malaria is, therefore, to be regarded as one of the water-borne diseases.

Dr. Thin objected to this hypothesis of Dr. Manson, adducing, among other arguments, the fact that in Sierra Leone malarial fever is exceedingly prevalent, but mosquitoes are few. He agreed, however, with Dr. Manson, if it be admitted that these insects are the intermediate host, that drinking-water probably forms the means of communication to man. He believed that the flagellæ play some part in the life-history of the organism, though he was not yet prepared to say what, and are not, as asserted by Marchiafava, due to the convulsive movements of the protoplasm in its death-struggles.

In reply Dr. Manson said that the parasite must have some third form not yet discovered in which it can remain latent in the body for a long time, until the conditions favorable for its development occur, at which time the patient develops an attack of fever. While he recognized the fact that there were many objections to his theory, yet he hoped, with the more complete investigation of what was as yet an entirely new field, that these would be removed.

Exophthalmic Goitre.—Dr. A. Foxwell reported a case of acute exophthalmos which had recently been under his care, in which pronounced changes were found post mortem in the brain. These changes were the following: 1. Chronic inflammation and sclerosis of the pia, covering part of the vermiform process, and of that covering the fourth ventricle and also of the middle commissure of the third ventricle. 2. Acute softening of the surface of both thalami. 3. Excessive vascularity of the surface of the brain of the internal capsule, of the cerebellum, and of the medulla—in the middle of the medulla, at any rate—leading to occasional hemorrhages. 4. Sclerotic changes, involving portions of the tegmen, pyramids, and the nuclei of the fasciculus gracilis and cuneatus, and of the tenth pair of nerves.

Thyroidectomy.—Dr. George R. Murray then read a paper upon the effects of removal of the thyroid gland in the lower animals, and said that these effects in rabbits were strikingly like to the symptoms of myxœdema in man. He showed a number of photographs illustrating animals operated upon, in which the skin lesions, the swelling of the neck, the apathetic appearance, etc., were well shown. These symptoms, he held, were very similar to those observed in the human subject of myxœdema.

Syringomyelia.—Dr. J. H. Targett presented a communication on "Syringomyelia and Joint Disease," in which he reported a number of cases of this affection that had been under his care, in which the articular lesions were observed to bear a striking resemblance to those met within the arthropathies of locomotor ataxia. He likewise dwelt in some detail on the other manifestations of the disease, namely, muscular atrophy, trophic skin affections, the curious condition in which there is insensibility to pain and temperature changes, while the ordinary sensibility of the skin remains unimpaired.

The Nature of Cancer.—Dr. Braithewaite opened the discussion on this subject with a paper in which he contended that the cause of the disease was a mould fungus that he had discovered in cancerous tissues. This fungus was present in the soil of certain districts and was carried in the drinking-water, so that cancer was another of the increasing number of diseases that have been found to be carried in water.

This paper was discussed at some length by Mr. D'Arcy Power, Dr. Russell Wells, Dr. Bousfield, and Mr. Shattock, who held that Dr. Braithewaite's conclusions were based upon a misconception of the forms which he had observed in the microscopical examination of cancerous tissue. The appearances described by the reader of the paper were, they maintained, due to changes in fat cells and elastic tissue produced by the methods used in the preparation of the specimens, and they held that the so-called spores were in reality crystalline substances deposited in colloid media.

The Chemistry of Carcinoma and Sarcoma.—Dr. Hewlett read a paper on Ehrlich's diazo-reaction in cancer, in which he asserted that the micro-chemical reactions of the so-called cancer parasites are wholly unlike those of the coccidia, with which they are usually associated.

The discussion was continued by Mr. Blake, who read a paper on the "Occurrence of Cancer in Chalk Valleys," and by Dr. Herbert Snow, the title of whose communication was the "Insidious Marrow Infection of Mammary Carcinoma." The latter reported several cases showing the danger of this infection being passed over unrecognized, as might very readily happen, by reason of the ill-defined character of the symptoms.

In closing the discussion, Dr. Braithewaite said that the arguments of his opponents failed to convince him that he had made such a serious error as they seemed to think. Indeed, the cases reported by one of those who had taken part in the discussion bore out remark-

ably his theory of the water-borne nature of malignant disease.

SECOND DAY, THURSDAY, AUGUST 1ST.

Peripheral Neuritis.—The greater part of the session of the second day was occupied with the discussion on the pathology of this affection.

DR. SEYMOUR J. SHARKEY said that the symptoms of peripheral neuritis have long been known, and Graves suggested that they had their origin in disease of the peripheral nerves, but it was only in 1864 that Duménil showed that such a pathological condition existed in the disease. As usually happens, when a new field like this is opened up, a large number of conditions previously not understood have been attributed to this cause, and we shall probably have to strike from the list many diseases at present referred to inflammation of the peripheral nerves. The subject, indeed, is still in its infancy, and there are many things yet to be learned. It is a question whether we have not been trying to draw too sharp a line between the peripheral and the central nervous system; whether we have not been too anxious to limit the pathology of many of these diseases to the nerves, while the various agents which produce them cause alteration in the centres as well. Alcohol, lead, the poisons of acute specific diseases, and many others, are certainly productive of wide-spread central changes, at the same time that they specially affect the peripheral nerves. Another question is whether the condition is truly one of inflammation. Are we justified in speaking of a change in nerves as inflammatory in the absence of those vascular phenomena which are usually looked upon as proof of inflammation? The pathological condition found post mortem is often segmentation and breaking up of the medullary sheath and nothing more. This is called "parenchymatous neuritis." In other cases nothing at all is found. The speaker thought it would be more correct to speak of peripheral nerve-intoxication where nothing is found post mortem, of peripheral nerve-degeneration where the only change is breaking up of the white sheath of Schwann, and of peripheral neuritis when the vascular phenomena of inflammation are present as well. The granular degeneration of muscles, whether fatty or albuminous, and that of many cells in the body, such as those of the liver, is not the result of inflammation only. Why, then, should breaking up of the medullary sheath into droplets be called neuritis? It may or may not be true that we cannot yet separate these cases clinically, but it may be possible to do so some day. If this distinction between nerve-degeneration and nerve-inflammation were made, many cases, such, for instance, as are now sometimes classified as "dyscrasic peripheral neuritis" would receive a more reasonable explanation as cases of degeneration.

Again, it is possible that we have not learned to appreciate the significance of the changes in nerve-substance found post mortem. Lesions supposed to be those of parenchymatous neuritis have been found after death when there were no symptoms pointing to that condition during life. It is possible that ordinary post-mortem changes have been mistaken for pathological lesions. In multiple neuritis the peripheral ramification of the nerves are first and most affected. This may be because they are more exposed to the action of the poison, or perhaps less able to resist it than the more central portions. Another interesting point, the speaker said, is that certain poisons appear to have a special affinity for certain nerves.

In alcoholic neuritis the extensor muscles of the limbs, and especially of the legs, almost invariably fall first a prey to the poison; in lead-poisoning, the extensors of the fingers and wrists; in diphtheria, the muscles of the throat and internal muscles of the eye. Still more remarkable is it that the selective power of these toxic agents may exert itself on the motor filaments or on the sensory almost exclusively. In lead-poisoning, for instance, sensory alterations are hardly complained of at all, and the same is often true of diphtheria, whereas in cases of alcoholic neuritis a stage of the most acute sensory disturbance may long precede the advent of paralysis. Indeed, there is some ground for supposing that even the trophic and vaso-motor nerves may be specially picked out in some cases. There are grounds for supposing that the remarkable vascular and trophic changes which characterize Raynaud's disease are the result of a special affection of the vascular and trophic nerve-filaments or the centres from which they radiate. We do not know as much as we might about the so-called reaction of degeneration. The alterations which occur are very variable, sometimes being but slight, sometimes profound. In the latter case they indicate, no doubt, a very marked disorganization of nerve and muscle. But we do not know what the slighter changes or their absence may signify as regards the pathological changes in the nerves.

Now that it has been shown that atrophic paralysis may result from disease of the peripheral nerves, the question arises whether we have any means at our disposal enabling us to distinguish between anterior cornual disease and peripheral nerve disease. Again, cases of paraplegia due to an extensive affection of the spinal cord, in which, nevertheless, there is no alteration in sensation, are not uncommon, and similar affections of the spinal cord and its surroundings may result in paraplegia with pain and sensory disturbances. Dr. Sharkey asked how such diseases of the spinal cord were to be distinguished from peripheral neuritis. This has generally been done by the presence of an affection of the sphincters in the former and its absence in the latter. This, however, the speaker maintained, is not a safe criterion. He had lately had a case of painful paraplegia under his care in which the sphincters were involved, and in which nothing was discovered at the post-mortem examination. On microscopic investigation of the nerves proceeding from the pelvis an intense neuritis was found. Another question is that of the cause of the peripheral neuritis and muscular atrophy which occur in association with joint disease. This has not yet received a satisfactory explanation. Other points raised by the speaker, and which he hoped would some day receive a satisfactory explanation, were the absence of knee-jerk in many cases of diabetes, the cause of Raynaud's disease, the question whether peripheral neuritis ever gives rise to spasmodic affections, the possibility that many so-called functional diseases of the viscera are the result of temporary inflammation or degeneration of nerves due to the action of some poison.

DR. W. M. ORD spoke of the coincidence of anæmia, ulcer of the stomach, and valvular heart troubles. He had thought that possibly the presence of a gastric ulcer had caused nutritive disturbances in the heart, or perhaps the two conditions were due to a common cause —some nerve-lesion. The circular margin of ulcer of the stomach offered a presumption of its nervous origin.

Post-mortem Nerve-lesions.—DR. RUSSELL WELLS read a paper on "Post-mortem Degeneration of Nerves," in which he described the results of a study undertaken by himself and Dr. W. H. Wilson. In patients dying from various diseases quite apart from nerve-lesions, the appearance of the medullary portion, as seen under the microscope, varied according to the time after death at which the preparation was examined. The earliest changes were breaking up of the medullary sheath and variations in the readiness with which the nerve-fibres stained with reagents; the axis cylinders did not take part in these changes. The loss of the medulla gives rise to appearances which render the nerves indistinguishable under the microscope from nerves taken

from cases of neuritis. Dr. Wells said, however, that he had not seen as a post-mortem change rupture of the axis cylinder, which writers on neuritis describe as occurring in that affection. He was of opinion that the changes met with in neuritis are not always due to post-mortem decomposition, because in the case of animals in which neuritis has been produced artificially the nerves are usually examined immediately after they are killed, and yet the nerves show alterations in structure.

Dr. Mott thought that peripheral neuritis was of interest in view of the theory of Marie that it is due to modifications in the ganglion cell with which the nerve is in anatomical continuity. That in diphtheria changes occur in the cells of the anterior horn as well as in the nerves, and that the paralysis was in some instances permanent and associated with wasting, was in favor of this view. He believed that the reason why alterations in structure occurred in the end plates of motor nerves in peripheral neuritis was their remoteness from the seat of nutrition in the ganglion cell. Fibrous tissue met with around the nervous tissue in various cases of nerve-degeneration he believed to be secondary to that degeneration.

Dr. Ormerod suggested that, as Dr. Hughlings Jackson had shown that the smaller nerve-cells were more likely to be affected than the larger by poison, it was reasonable to assume that the smaller terminal fibres were more readily affected than the larger trunks.

Sir T. Grainger Stewart thought that an affection of peripheral nerves was the only explanation of the combination of the motor, sensory, and nutritive changes met with in this disease He thought the following clinical points were worthy of note: 1, The possibility of perfect recovery from so marked a lesion of the nerves; 2, an affection of peripheral nerves offers a ready explanation of the transitory paralyses met with in the early stages of locomotor ataxy; 3, the capriciousness of neuritis in the selection of nerves; 4, the not infrequent deaths in this disease due to the involvement of vital nerves. He said that hypodermic injections of strychnine, as soon as the first acute stage was passed over, were much more efficacious than the administration of the drug by the mouth.

Dr. Hamilton questioned the correctness of the nomenclature in peripheral neuritis, for he believed the appearances were entirely due to degenerative changes, and not to inflammatory processes at all.

Dr. Saundby was of the opinion that in many cases the changes were in reality due to inflammation of the nerves. He evidenced in support of this view the tenderness which occurs over the nerve-trunks in certain forms of neuritis, as well as the swelling which accompanies this tenderness.

Vaccinia and Small-pox.—Dr. S. Monckton Copeman read a long paper in which he gave the details of a successful attempt to cultivate the micro-organism of variola and to inoculate therewith a calf, obtaining from the latter a lymph with which a successful vaccination was performed. He had discovered a year ago the presence in specially stained specimens of vaccine lymph, taken before full maturity of the vesicles, minute bacilli, often in considerable numbers and in practically pure culture. These bacilli cannot be found in mature lymph, for the reason probably that they have given place to spores. After several attempts he succeeded in cultivating this micro-organism in the hen's egg. He began by first cleansing the surface of the egg with corrosive sublimate solution and afterward with alcohol, and then breaking a small hole in the shell by means of a sterilized needle and forceps. Through the opening thus made he mixed the yolk and albumin of the egg by means of a platinum needle, and then carried out the inoculation by means of a glass capillary pipette which had recently been drawn out in the blow-pipe flame. For these inoculations he employed variolous crusts which were rubbed up in a small glass mortar with a minimal quantity of sterilized normal saline solution. After the inoculation the small hole in the egg was closed up, and the eggs were placed on beds of cotton-wool and kept in the incubator at a temperature of 37° C. Here they were left for varying periods of time, a month being the period which was eventually found to be that which was most desirable. On opening an egg thus treated the speaker found a creamy material, which had replaced the ordinary egg contents. This material, examined under the microscope, appeared to be a pure culture of one organism only—viz., a bacillus which morphologically was not to be distinguished from the bacillus previously found in early vaccine lymph.

Attempts to grow this bacillus in various subcultures were invariably unsuccessful, but inoculations of calves gave positive results. With the lymph obtained from these calves children were vaccinated and the operation "took" well. The experiments, however, were not as satisfactory as they might have been, for it was necessary to use calves at a vaccine station which were at the same time vaccinated in some other part with the calf lymph employed at that station. Every possible precaution was taken in the way of sterilizing instruments and keeping the incisions protected as far as possible against accidental inoculation with lymph from some part of the same or other calf into which the ordinary animal vaccine material had been inserted. Nevertheless, it is possible that, in spite of all precautions, accidental inoculation with ordinary lymph may have occurred; or possibly the simultaneous inoculation of the calves with egg culture and with ordinary vaccine lymph may have in some way influenced the manifestation witnessed on the areas wherein the egg lymph was inserted.

The experiments would, however, be repeated with all these possible sources of error eliminated. Should these prove successful it is not too much to believe that we may eventually be able to elaborate not only a vaccine but an antitoxin for treatment of a person actually suffering from the disease, as we now treat the subjects of diphtheria.

Dr. Haughton thought that there was something more than mere microbic infection in the production of small-pox—that insanitary conditions were of nearly, if not quite, equal importance.

Dr. Denham had noticed that the vaccine from a calf approaching puberty was not so efficacious as that taken from a younger animal. He confirmed a statement which had been made by the reader of the paper that the mixing of lymph with glycerine and storing for some time led to the total destruction in it of saprophytic organisms.

In closing the discussion, Dr. Copeman, referring to vaccine points, said that they are bad, and that if used at all they should be made of celluloid, which can be sterilized, rather than ivory, which cannot be so satisfactorily sterilized owing to the interstices in it. In answer to a question, he stated that he did not believe that the psorosperms produced in the rabbit's cornea after inoculation had anything to do with the production of small-pox, and he said that they had never been found in vaccine lymph itself.

Pernicious Anæmia.—Dr. Hunter then read a paper on this affection in which he held that it was a disease *sui generis* and not related to the forms of anæmia associated with cancer and other diseases. His reasons for this conclusion were that there are not the same pathological changes in the blood in the latter as in pernicious anæmia, and that the extreme degree of blood change is always associated with marked pathological changes in the liver, kidney, and spleen, such as are not found in traumatic and other anæmias. Dr. Stockman had advanced the view that the main difference between pernicious anæmia and other forms of anæmia lies in the presence of hemorrhages in the

former and not in the latter, but the speaker said that he had failed to produce pigment deposits in the liver by injecting large quantities of blood into the peritoneal cavity of rabbits, and further, that in his experience hemorrhages in pernicious anæmia were very rare except into the retina and meninges.

Dr. Copeman thought that urobilin occurred only in those cases of pernicious anæmia which were associated with high temperature, and he thought that there were other cases in which just as profound changes occurred in the blood without the deposition of pigment in the liver.

Third Day, Friday, August 2d.

Lymphadenoma.—Dr. W. G. Spencer opened the discussion on this subject. The term, he said, was one applicable to all neoplasms composed of lymphadenoid tissue resembling in structure a lymphatic gland. Until our knowledge of these growths is enlarged it is better to rest satisfied with some general term of this kind. In a study of the etiology of the affection we may follow the analogy of tuberculosis and distinguish a local disease, lymphadenoma, and a general disease, lymphadenomatous. There are two types of the local affection. The first is simple lymphadenoma, which is simply an overgrowth of lymphadenoid tissue excited by some cause acting continually upon this tissue from the surface of the skin or mucous membrane. In malignant lymphadenoma there is a tendency in the cells to proliferate without the incitation of the continuous local irritation. The connective-tissue cells of the septa and capsule also participate in this overgrowth. Since there is no source of irritation, acting from without, which is sufficient to keep up the continued multiplication of cells, the cause must be looked for within the tumors themselves. Then there is the general affection, lymphadenomatosis, in which lymphadenoid tissue, wherever existent, is attacked, and in which we find also the general symptoms cachexia, anæmia, hemorrhages, irregular temperature curve, and an increased proportion of white blood-cells. Hodgkin's disease, lymphatic cachexia, splenic leucæmia, and various other names have been applied to this disease, but they are confusing and ought to be dropped. If a classification be attempted, it is better to adopt one based upon the way by which the virus, if there be one, enters the system. Thus we find cases in which the infection apparently occurs through the intestinal tract, others in which the channel is the lungs. Much experimental work is being done to determine whether there is a micro-organism acting as the cause of the disease, but there are still the usual contradictory and negative results inseparable from the early stages of such investigations.

Mr. J. Jackson Clarke said that in his opinion there was no distinction to be made between Hodgkin's disease, lymphosarcoma, and lymphadenoma. He thought lymphadenoma frequently went on to true sarcoma. In cases of deep-seated mediastinal lymphadenoma, a diagnosis was often made possible by infiltration of the skin. He had found lymphomatous growths in various organs in leucæmia. Lymphadenoma was often found associated with osteoarthritis and gout.

Dr. Murray Leslie related a number of cases showing the existence of a close relationship between lymphadenoma and leucæmia and splenic anæmia. The number of leucocytes and hæmocytes depends on the relative involvement of blood-destroying structures. Dr. Leslie believed that lymphadenoma is an infectious disease, and offered the following arguments in favor of this hypothesis: 1, Certain cases seem to owe their origin to exposure to foul air; 2, micrococci and other organisms have been found in the affected structures; 3, the close analogy which exists between this and tuberculosis and other microbic diseases; 4, affection of the cervical glands would point to infection by the mouth, of the mediastinal glands by the lungs, and of the mesenteric glands and Peyer's patches by the alimentary canal; 5, pyrexia and night sweats are present, as in other diseases of micro-parasitic origin; 6, the beneficial effects of arsenic are probably to be attributed to its germicidal action, and are comparable with the action of mercury in syphilis. The speaker would place lymphadenoma among the granulomata, along with syphilis, tubercle, and leprosy.

Dr. G. N. Pitt said that true lymphadenoma consists of an adenoid overgrowth limited to adenoid tissue, which never fungates or infiltrates, and which destroys only by pressure on vital structures. He had seen tubercle and lymphadenoma associated, and he thought the difference between neoplasms and infectious granulomata might turn out to be less than at present supposed. When there is leucocytosis the spleen is more frequently enlarged, though, on the other hand, a temporary and variable leucocytosis may occur apart from splenic enlargement. He did not agree with Dr. Spencer, who had said that if improvement took place under the use of arsenic, the disease must be lymphadenoma, for he had seen an undoubted spindle-celled sarcoma melt away under the action of this drug.

Dr. Snow said there were three distinct affections characterized by enlargement of the lymphatic glands, viz., 1, Simple lymphoma; 2, Hodgkin's disease, a general enlargement of glands throughout the body, often occurring during pregnancy or after exposure to cold or wet, accompanied by elevation of temperature, and shown under the microscope to be a cirrhosis of the gland; 3, lymphosarcoma or lymphocarcinoma, a true cancer, and showing all the features of a malignant growth, viz., cell proliferation, erosion of adjacent tissues, and progressively fatal tendency.

In closing the discussion Dr. Spencer said that lymphoma should be applied to a growth of lymphatic vessels, lymphadenoma to one of the lymphatic glands. He did not feel at all certain as to the microbic origin of the neoplasms. As to leucæmia, that was a symptom only and not a disease.

The Diazo-reaction.—Dr. Hewlett then presented a communication on Ehrlich's diazo-reaction of the urine in typhoid fever. The same reaction, he said, is obtained with morphine even in a 1 to 5,000 solution. This was the only foreign substance, however, with which he had been able to obtain a reaction. The reaction can be obtained as early as the sixth day in cases of typhoid fever, but the speaker did not regard the test as especially reliable or as one of positive diagnostic value; negatively, however (its absence showing that the affection was not typhoid fever), he regarded it as very valuable.

Microbes in the Air.—Dr. St. Clair Thomson reported the results of a number of experiments conducted in collaboration with Dr. Hewlett, to determine the fate of micro-organisms in the respired air. They had found that fewer bacteria were inhaled through the nose in ordinary breathing than was commonly supposed, and that most of these were arrested at the entrance to the nostrils. Indeed, the mucous membrane of the nose, in health, was truly aseptic.

Hypertrophic Pulmonary Osteoarthropathy.—Dr. F. R. Walters reported a case of hypertrophic pulmonary osteoarthropathy, and presented the patient to the Section. He thought that the disease was the result of the action of toxins upon the tissues. It was essentially different from acromegaly.

A paper on "Psorospermosis" was then read by Drs. Danett and Surveyor, and another on the "Growth of the Choleraic Vibrio and other Bacilli in Sunlight" by Dr. Westbrook.

After a vote of thanks to the presiding officer, Dr. Wilks, the sessions of the Section were brought to a close.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON ORTHOPEDIC SURGERY.

Stated Meeting, May 17, 1895.

L. W. HUBBARD, M.D., CHAIRMAN.

Bending of the Neck of the Femur.—DR. ROYAL WHITMAN presented a boy, about eleven years of age, with bending of the neck of one femur, causing considerable adduction, but not to the degree which he had seen in some other cases. The deformity was a rare one. He had seen only six cases. There was limitation of motion in all directions, and some pain was present, sometimes very severe. These cases were usually mistaken for hip-disease or dislocation.

Congenital Dislocation of the Shoulder; Replacement after Trimming the Head of the Humerus.—DR. A. M. PHELPS presented a boy, nine years old, who after birth, the labor having been instrumental, was found to have dislocation of the humerus backward under the spine of the scapula. The doctor suggested that it be left until the child got older, and later another physician pronounced it a case of paralysis. Other physicians and surgeons had since seen the boy and were of opinion that an operation was not advisable. After consultation with Drs. Gibney and Morris, Dr. Phelps decided to operate. Sixteen days ago he cut down on the head of the bone, which was underneath the spine of the scapula, liberated it, felt of the glenoid cavity, found it nearly as large as a quarter of a dollar, considered whether to enlarge the cavity or trim the head of the bone, and decided to do the latter, for the reason that, had he enlarged the cavity it would still have been necessary to shorten the humerus in order to replace it and the result would have been, in bringing the two raw surfaces together, anchylosis of the joint. The case seemed to possess some unique features, differing, of course, from old dislocations forward under the acromian or backward into the axilla, and also in the manner of adapting the articulating surfaces to each other.

The Treatment of Postural Deformities of the Trunk by Means of Rapid and Thorough Physical Development.—This was the title of the paper of the evening, by DR. JACOB TESCHNER. He commenced by saying that the results of the different forms of treatment of postural deformities have been generally slow and unsatisfactory up to the present time. He claimed that a weakened or rudimentary condition of certain muscular groups, or of the muscular system generally, is the most important etiological factor in these deformities. Development of the full strength of the individual, of the entire muscular system, and thorough muscular education, are the desiderata in treatment. The amount of benefit derived from gymnastics is in proportion to the will, strength, and development which are necessary to partially or completely reduce a postural deformity. Gymnasium and class work for deformities are strongly objected to. So are all supporting or immobilizing appliances, because they interfere with perfect muscular freedom.

The important points to be observed in the development of strength and muscle, and in muscular education, are correct attitude, ease, grace, and rhythm of motion, and automatic and independent and full action of only those groups of muscles which are called into play by the performance of each separate exercise, and each group of muscles automatically exercised until it is thoroughly tired. No muscle can be properly developed unless it be tired by frequent and uninterrupted automatic contractions and relaxations.

Taking the stand-point that: 1, Lack of strength and lack of muscular development; 2, habitual faulty position with superimposed weight; and 3, lack of co-ordinating power or lack of muscular control, are the more potent etiological factors in producing deformities. He corrects deformities by reversing these conditions: 1, By developing the muscles and their strength; 2, by acquiring an habitually corrected position with superimposed weight; and 3, by educating all the muscles to proper co-ordination and complete control.

A series of twenty-six dumb-bell exercises were demonstrated by a nude patient. Heavy work with dumb-bells weighing from five to forty pounds each, and with steel bars weighing from twenty-six to seventy-eight pounds, was also shown by different patients. An exact record is kept of the work done by each patient at each visit. After the work they are showered with cold water and rubbed down with alcohol. The heavier the weight held above the head, the more the patient must exert him- or herself to improve the attitude in order to maintain the equilibrium; hence the greater the weight, the greater the correction of the deformity.

Nine cases were reported, with charts and photographs, of which five were exhibited. One case of deformity of the sterno-costal articulations of the right side, and six cases of mild curvatures and round-shoulders practically cured, and two cases of old and firmly fixed scolioses (one from infancy) which were greatly improved. All the patients improved in general health. Measurements and strength tests were made according to the Sargent system and recorded upon the Sargent charts. The chest capacities, chest depths, girths, breadths, and strength tests are generally increased, the abdominal depths are decreased, and the feet, the foundation of correct posture, are improved, inasmuch as all flat feet become shorter, and the normal feet grow. No bad effect upon the hearts of patients could be detected, and their general improvement, and increase in weight, should prove that they are not overworked.

Employs Mechanics and Exercise.—DR. BRACKET, of Boston, said he had had no practical experience with the particular method described by Dr. Teschner. He looked upon lateral curvature as a vice of growth. While the patient had assumed an abnormal position, growth went on and made the faulty position permanent, unless some means were taken to correct it. The spine being more flexible on one side than the other, tended to bend toward the concavity and to become rotated. Although during active physical exercise the spine could be made to straighten itself in a measure, and this process could be repeated, yet during the intervals there was a tendency to resume the abnormal position. He believed, therefore, in mechanical treatment, supplemented by physical development. By apparatus one could correct the faulty position and maintain it in a positive way, while by exercise growth could be encouraged in the corrected position and overcome the tendency to relapse. A careful record should be kept of one's cases both by outline and by photograph.

The Dangers of the Proposed Method.—DR. H. A. WILSON, of Philadelphia, thought it would be impossible for the physician to give personal supervision of this work and treat many cases. If it were transferred to a masseur or gymnast, it would lead to such abuses as were seen in all cities. He must acknowledge that he had felt some anxiety when he witnessed the small patient going through such severe labor, and the danger would certainly be real should it be prescribed without the immediate supervision of a doctor. Gymnastic exercises without intelligent supervision often led to asymmetrical development of the muscles of the body and to deformity.

DR. J. YOUNG said Dr. Teschner's plan of treatment of these cases was entirely opposed to that which he was in the habit of employing. He was accustomed to prescribing the Swedish movement cure, which implied a moderate exercise of the desired group of muscles, giving time also for compensatory development of the muscles of the heart and respiration. He had found that unless development of the muscles under the control of the will was brought about slowly, there would

not be sufficient compensatory development of the heart and respiratory muscles. The treatment by muscular exercise, therefore, should take time. The use of massage was important, and electricity had its place. The condition of rotation was one which likewise deserved special attention.

Dr. R. W. Lovett, of Boston, thought the greatest objection to the treatment described in the paper was that the exercise was of the two sides equally. He was of opinion that special attention should be given the weaker muscles. While gymnastic treatment was powerful for good, it was equally powerful for evil. The more he saw of gymnastic treatment in lateral curvature, the more he became impressed with the necessity for extreme care. Two years ago he had first put some cases under the Swedish movement cure, the Lyng system, by a lady who had had special opportunities, and although he was at first a sceptic, he had since become convinced that the method was a valuable one. The weaker muscles were picked out and exercised and strengthened, while the stronger opponents were isolated. The patients came twice a day. Nothing but a cot and a bar were necessary. Milder cases might become perfectly straight in the course of some months. Forcible correction was also resorted to in other than the mildest cases. He felt like Dr. Wilson, that there was some danger connected with the severe form of exercise prescribed by Dr. Teschner.

Dr. H. Lilienthal had seen some of Dr. Teschner's work, and believed that it would accomplish what had been claimed for it.

Dr. Reginald H. Sayre thought the method was liable to result in undue muscle strain. The direction given the patients to breathe easily and regularly during the exercises, could not be followed while the various muscles of the body were under strain; it was natural under such conditions to hold the breath. Young tissue, as well as old friable tissue, was liable to overstrain and injury. There was greater danger of harm in the deformed patients than in persons of normal form. In some instances there was practically no muscle to work upon, and it was necessary to give the bones proper support during growth in order to avoid further deformity.

Dr. Samuel Ketch thought minor deformities could be corrected by ordinary means. There was greater difficulty in rotary lateral curvature. The rotation deserved particular attention, and no case could be considered cured until this element had been eliminated. Regarding rapid physical development by muscular exercise, he might say that during the past year he had watched persons training in a noted gymnasium of the city, and had observed that deformity was not uncommon. One of the teachers, a physician, showed lateral curvature of the spine. It seemed to him that the heavy exercise put upon small children for a short time would result deleteriously in the future. It was a question whether the gain which had been made in the cases reported would be retained without some support or continuing the treatment. He thought most good would come from increasing the lateral flexibility of the spine and keeping the patient in as good position as possible.

Dr. Teschner closed the discussion. Regarding apparatus, he had tried it and had found that while it had some effect in changing the contour of the spine, it was less in correcting the seat of the deformity than in producing deformity where none had existed before. Some of the gentlemen had spoken of dangers connected with the physical training which he had described. On the other hand, he could point to danger from the use of mechanical treatment, and mentioned an instance or two in which syncope had resulted from the pressure upon the sternum, etc.

As to flexibility of the spine, he claimed that the method which he advocated was most efficient in this direction. One could not wait for correction by the development of the muscles which were at fault when, as sometimes appeared to be the case, they were scarcely present even in the rudimentary state. He saw no reason for slow correction of the deformity when it could be brought about rapidly. It was a mistake to suppose that the voluntary muscles were developed without proportional growth of the cardiac and respiratory muscles. The lung capacity had been markedly increased, there had been no cardiac symptoms, and beyond doubt the heart had developed in proportion to the rest of the muscular system. He impressed the fact that he gave each case his personal attention, besides having an experienced assistant.

Surgical Suggestions.

Gastrectomy.—(1) The smallest amount (a few drops in the first case) of anæsthetic possible should be used; (2) all antiseptics should be avoided in the abdominal cavity; (3) the extra-peritoneal method of resection should be adopted, the posterior part of the ring of sutures is surrounded by gauze, and the situation of the remaining sutures should be permanently extra-peritoneal, the anterior wall of the stomach is covered in by a flap of skin; (4) the patient should be fed early by the mouth.—Langenbuch.

In Prolapse of the Rectum, sometimes much relief is obtained by injecting, before going to the closet, from ℥ vij. to ℥ viij. of warm water, and afterward an ounce of cold water, allowing it to remain.—Keen.

Treatment of Burns.—

Aristol	5–10.0
Olive-oil	20.0
Vaseline,	
Lanoline	āā 40.0

—Haas.

Gonorrhœa.—

Perchloride of mercury	1 part
Antipyrin	100 parts
Distilled water	10,000 parts

The injection should be used four times a day and retained as long as possible. The addition of antipyrin prevents smarting.—Vatier.

Chordee.—

R. Ex. opii	gr. j.
Camphoræ	gr. x.
Ol. theobrom	q. s.

M. et ft. Suppository No. I. Sig.: Use at bedtime.

—Ricord.

Gonorrhœa. Second Stage.—

R. Hydrarg. chlor. corros	gr. ½
Acidi carbolici	ʒ iss
Zinci sulpho-carbolate	gr. xxiv.
Boro-glyceride (fifty per cent. sol.)	f ʒ ij.
Aquæ rosæ q. s. ad.	f ʒ viij.

M. Sig.: Use as injection after urinating.

—White.

Women affected with metritis or displacements often suffer with dry cough without any disease of the respiratory organs.—Pozzi.

Incontinence of Urine.—

R. Sodii benzoatis,	
Sodii salicylatis	āā gr. xx.
Fld. ext. belladonnæ	gtt. ij.
Aquæ cinnamomi	ʒ iv.

M. Sig.: A teaspoonful four or five times daily.

—White.

Tricophytosis.—

Chrysarobin	gm. 10 to 25
Salicylic acid	gm. 5
Ointment of styrax	gm. 5
Ichthyol	gm. 5
Simple ointment	gm. 5

—Du Castel.

Cold Bathing during menstruation is a beneficial measure, provided women accustom themselves to it by bathing every day for at least eight days before the period. Houzel holds that cold salt-water baths facilitate the menstrual flow, increase the duration of genital life, and increase fecundity.—Depasse.

Salol in Non-parasitic Sycosis.—Twenty to forty grains to the ounce of petrolatum were employed.—Cantrell.

Fractures.—The object of the surgeon in treating fractures about the joints should be: 1. To allow free circulation in the limb. 2. To obtain complete rest for the injured structures until they assume their normal condition. 3. To posture so that the callus exudation shall not unduly hamper the joint movements.

Apoplexy.—Apoplexy occurring in early adult life is much more frequently due to syphilis than embolism, and syphilis is a factor in a third of all apoplexies, at least in large cities. Apoplexies are increasing in disproportionate frequency. The disease does not especially affect brain workers if they live temperately, but rather spares them. An attack is sometimes a conservative agent, calling a halt to excessive activity and intemperate living, and actually prolonging life. About one-fourth of those stricken with apoplexy die from the attack (hemorrhages being the most dangerous, thromboses, especially syphilitic, being least so). The average duration of life of those who have and survive one shock is over five years. The chances of a second attack before the fourth year are always considerable, yet do not amount to fifty per cent. and are inconsiderable so far as hemorrhages are concerned. Thromboses are much more apt to recur than hemorrhages.—Dana.

Acute Typhlitis.—I have rarely seen a case of acute typhlitis in which the large bowel was not full of old fæces, and I have still more rarely seen a case in which the colon could be unloaded in which recovery did not take place. So true is this, that of late years I have nearly always regarded the emptying of the colon as ending the immediate danger to life, provided, of course, that the inflammation has not proceeded to the point where an abscess has formed or perforation taken place.—Stoker.

Bactericidal Properties in the Vaginal Secretion of Pregnancy.—Not only is the vaginal secretion in normal pregnancy free from pathological germs, but it has a distinct germicidal power. Experiments were made in a great number of pregnant women by introducing into the vagina different kinds of germs, and then at stated intervals withdrawing secretion for examination, and it was found that the secretion was equally active whether the vagina contained the "normal secretion" or the so-called pathological secretion described by Doederlein. In these experiments the streptococcus was killed first, the staphylococcus and the pyocyaneus needing almost twice as much time. The vagina was found clear in two days at longest. Syringing the vagina with antiseptic solutions has the effect of reducing or completely destroying its germicidal powers. Hence prophylactic syringing should be given up. It does no good, and much harm. Even in pregnancy with gonorrhœal infection it is best omitted. Disinfection of the internal genital passages should be abandoned as part of the routine of antiseptic midwifery.—Kroenig.

Corneal Ulcer.—Aristol is recommended in powder form for indolent corneal ulcerations with suppurating base. It is thickly applied with a brush and the eye kept closed for a time. A five per cent. ointment is useful in ulcerative blepharitis, being preferable to the yellow precipitate ointment on account of its causing less irritation. This ointment has given good results in obstinate, recurring hordeola when rubbed into the edges of the lids at night.—Heuse.

Facial Erysipelas.—

℞ Ergotine ..... gm. 1.30
Liquid extract of ergot ..... gm. 8
Lanolin ..... gm. 15
Fresh lard ..... gm. 45
M. For external use.

—Lees.

Novel Treatment of Fracture.—Cut down on every oblique fracture of the leg, expose the fragments, bring them into accurate apposition, drill holes and fasten by steel screws. There is immediate relief of pain by this method, absence of tension and discomfort due to extravasation of blood into the tissues, and shortening of the period of treatment. This is especially to be recommended in the laboring man, to whom time is money.—Arbuthnot Lane.

Rhythmic Tractions of the Tongue.—1. Lingual tractions should be moderate to produce their effect; tractions too forcible cause an inhibition of the respiratory reflex. 2. The best mode of practising traction is to use no special instrument, but to seize the point of the tongue with a bit of linen between the fingers. 3. The process is not superior to other methods, especially insufflation, and that it would be culpable to employ it exclusively.—Pinard.

Post-Partum Hemorrhage.—Flooding after the application of the forceps must always be expected, since the instrument is usually employed because of uterine inertia, a source of hemorrhage. The danger comes when the placenta is expelled.—Tarnier.

Painful Fissures of the Nipples have, for some time past, been treated by the application of cocaine, either in the form of an ointment or a liniment. It has been found, however, that when thus employed, the secretion of milk is diminished and the erection of the nipple prevented. These objections have led Dr. Joire, of Lille, to use cocaine with the direct object of checking the secretion of milk when necessary. He recommends a solution of one grain of cocaine in ten grains of water and ten grams of glycerine, and he advises that this should be used as a lotion to the nipple five or six times a day. He explains the arrest of secretion by the anæsthesia of the nipple which results.—*The Lancet.*

Disinfection of Knives for Operation.—Boiling in soda solution is required for complete asepsis of operating knives. The latter are not rendered dull by the treatment, but are doubtless often injured by contact of the blades with other instruments and with the vessel. Small narrow tin boxes containing racks in which the knives may be placed with edges free should be used. The bottom of the box has several perforations. The boxes are placed in a vessel of water and boiled. Knives should afterwards not be placed in carbolic solution, which dulls. Care is not required to have an exact 1 per cent. solution of soda, because a stronger solution does not injure. A chemically pure soda should be used. If powdered an even tablespoonful; if crystallized three tablespoonfuls to the pint is sufficient.—Ible.

Silver Sutures in Hernia Wounds.—For about one year I have sewed all of my hernia wounds with silver wire and have covered them with silver foil. Without exception the wounds have healed absolutely *per primam.* Not a single stitch-abscess has been observed either during or subsequent to the healing of the wound. Such absolutely perfect healing of the hernia wounds we have not had heretofore, and I am convinced that the use of silver as a suture material has contributed somewhat to this result.—De Garmo.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

THE LATE DR. BRISTOWE—HEALTH OF LONDON—DR. BRUNTON'S PROMOTION — THE COMMANDER-IN-CHIEF.

LONDON, August 31, 1895.

THE death of Dr. Bristowe will have been learned with regret on your side of the Atlantic as well as ours, for his reputation as a teacher and writer, as well as a sound physician, has for many years been very extensive, and not a few of the visitors from the States have observed his clinic at St. Thomas's Hospital. Dr. Bristowe's health had been failing for two or three years—indeed he had scarcely been the same since the shock of his brother's death, in 1892, soon after which he was struck down by influenza. This left a legacy of ill health. He went to Monmouth for a change, and there the end came within a week of his arrival, heart-failure being the immediate cause. Dr. Bristowe was the son of a medical man and was born in 1827. He was educated at King's College and St. Thomas's Hospital, and graduated at the University of London. He distinguished himself as a student, and his subsequent career was always onward. He received many honors in the profession and bore them with becoming modesty. His "Theory and Practice of Medicine" appeared in 1876 and at once took high rank as a text book—a position it has maintained through the seven editions that have been called for. His book on "Diseases of the Nervous System," which was published in 1888, was a collection of important cases, and I believe only failing health prevented him from bringing out similar works on other diseases. He was president of the Neurological Society, and had occupied the same office in other societies. The nervous system seems to have been a favorite study with him, and his opinion on nerve diseases was regarded as one of the most reliable to be obtained. As may be noticed in his writings, he was reluctant to prescribe drugs unless he felt there was a clear indication for them. Hence in some quarters he was looked upon as a sceptic in therapeutics; and yet that idea scarcely represents his attitude. Students found that if they could give a solid reason why, he was ready to approve their suggestions; but he was opposed to the routine ordering of medicine, and would often limit his prescription to a bitter infusion. His clinical teaching was of the very highest order, and he devoted himself to it with a zeal and patience which was greatly appreciated. Among extra professional accomplishments may be mentioned painting, and it is whispered that in youth he had thought of following art as a calling. He was also somewhat of a poet, and published a volume of verses.

Diphtheria is still increasing. Small-pox remains without any marked tendency to decrease. A suspected case of cholera occurred last week, but bacteriological examination showed that it was not so.

Dr. Lauder Brunton has at last got his advance, and becomes full physician to St. Bartholomew's Hospital—where he has been assistant physician for over twenty years. Among all the inequalities that occur, the long waiting at Bartholomew's ought to be remedied. It was at this hospital that the late Mr. Wormald was kept in a subordinate position when he had become President of the College of Surgeons. Verily doctors do give their gratuitous services freely enough for the public to form a poor estimate of their value.

The Duke of Cambridge is really to give up the commandership-in-chief. The army medical staff thus gets rid of one who never appreciated its services. Lord Wolseley is to succeed, but he is not much of a friend to the Medical Department, I fear.

ALKALINE INJECTIONS IN GONORRHŒA.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: Dr. Philip Jaisohn's article in the issue of your journal for September 7, 1895, entitled "Alkaline Injections for the Treatment of Gonorrhœa," I have read with great satisfaction.

Ever since 1882, that is, since I read a certain paper of Küchenmeister, I have treated the first stage of manifested gonorrhœa by means of injections of diluted lime-water (1 to 4), and have found that Küchenmeister was quite correct in saying that by such treatment we are enabled to do away with those well-known painful symptoms of the acute inflammation of the urethra. Küchenmeister claims that the lime-water acts on the infected mucous membrane of the urethra even more promptly than on diphtheritic membranes of nose and pharynx, namely, by dissolving the superficial layer, and thus removing the nutrient soil for the microbes.

The theory of this treatment impressed me favorably, and since I found it confirmed by practical experience I often spoke to specialists on genito urinary diseases about it, but none would ever pay attention to my remarks.

I ask the patients to repeat those injections frequently every hour in the beginning, if they can conveniently do so, and continue less frequently for three or four days. Precaution is to be taken that the water for dilution be distilled, and that the solution is not deteriorated by exposure to air.

A. ROSE, M.D.

336 EAST FIFTEENTH STREET.

New Instruments.

THE STOMACH-DOUCHE AND ITS USES.

BY M. GROSS, M.D.,

NEW YORK.

WHILE in ordinary lavage of the stomach the fluid is carried into the organ by its own weight, this is effected in the case of the stomach-douche by simple elevation of the reservoir or by certain pressure apparatus. The stomach-douche, therefore, is intended to irrigate the organ with fluid under great pressure, so as to exert a therapeutic effect upon the walls of the stomach.

The first favorable effects of the stomach-douche in gastralgia were reported by Malbranc,[1] from Kussmaul's clinic, and since then favorable results from its use have been noted also by Ewald, Boas, and others in various, particularly nervous, affections of the stomach. To Rosenheim[2] belongs the credit of having rehabilitated the stomach-douche, and he, too, was the first to point out the great difference between a simple lavage and an irrigation by means of a douche.

Ordinary lavage is performed for the purpose of cleansing the interior of the stomach of the remnants of food encumbering its walls and causing, besides, various functional disturbances by their decomposition. Equally important is the cleansing of the stomach of mucus, which adheres more or less firmly to the wall and tends to neutralize any existing diminished secretion of hydrochloric acid, while it also prevents the contact of food, agitated by the gastric peristalsis, with the wall of the organ, thereby diminishing or abolishing the stimulation necessary to the secretion of hydrochloric acid. It is customary, too, to perform lavage in order to strengthen the muscular coat by the stimulation of the gastric wall, or to increase the secretion,

[1] Berl. Klin. Wochenschr., 1878, p. 41.
[2] Therap. Monatshefte, August, 1892.

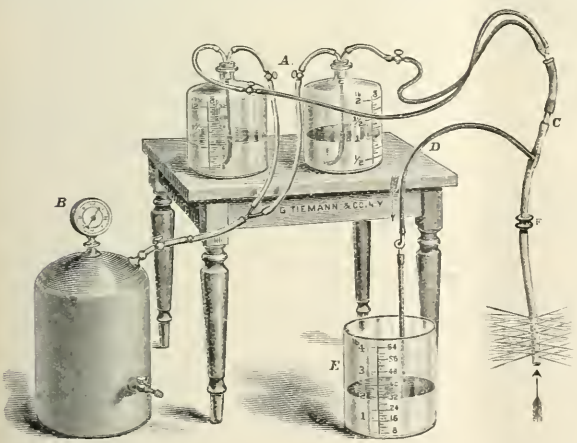
or again, in other cases, to inhibit an increased secretion (*e.g.*, in continuous acid secretion) by the introduction of chemical solutions. But is it possible to attain the objects here enumerated by ordinary lavage of the stomach?

The stream of liquid introduced within the stomach through the tubes generally used strikes merely the portion of the wall adjoining the opening of the tube with a slight pressure. Moreover, the accumulated fluid can but unnecessarily encumber the organ; the agitation of the fluid within the stomach, which we are able to effect by elevating the reservoir and then rapidly lowering the tube, is, as is well known, not always sufficient to thoroughly cleanse the interior of the organ; tough, adhering mucus is either not reached by the agitated water or else the force is not sufficient to detach it.

All this proves that we may expect perfect results from simple lavage of the stomach only in exceptional cases; but it is different when the fluid introduced may be forced over all portions of the interior surface of the stomach by corresponding pressure. This is effected by the stomach-douche by irrigation of the cavity of the organ.

Rosenheim employs for gastric irrigation a tube devised by him, provided with numerous small openings in its lateral wall and a larger opening at its end; the latter opening has a smaller diameter than the tube, so that the efflux should be rather restricted; the terminal opening serves at the same time for a rapid evacuation of the fluid introduced. But this tube, too, does not come up to our expectations, for the lateral pressure, being diverted, is diminished by the terminal opening; besides, it is impossible to prevent overfilling of the stomach, in which case the tube is submerged and the effect of the lateral spray is thus counteracted. It is only an empty cavity of the stomach, which can be reached from every direction, that can be thoroughly cleansed and thus rendered more accessible for other therapeutic purposes.

The stomach-douche devised by me will satisfy all



the above-mentioned requirements. The description and mode of application of the apparatus will show its advantages. The apparatus consists of (1) two graduated bottles (*A*) of a capacity of one to two litres, in which the fluid to be employed is kept under constant pressure, easily regulated by means of a condenser (*B*) or an ordinary air-pump. Two reservoirs are supplied to enable the physician, if necessary, to irrigate the stomach alternately with fluids of varying temperature, or perhaps for rinsing after the use of a chemical composition. (2) A double tube (*C*); the external one, in the length of about five to six centimetres perforated in all directions by numerous small afflux openings; while the internal one (*D*), completely isolated from the outer, serves merely for the rapid, instantaneous afflux of the fluid. The fluid escaping through the inner tube is received into a graduated vessel (*E*) intended for the control of the quantity of fluid returned. Should the inner (return) tube be obstructed by remnants of food or mucus, slight expression or aspiration will suffice to restore the flow.

The tube is introduced as follows: Commencing behind at the eighth or ninth dorsal vertebra (the region of the cardiac orifice) the tube is measured along the back and the side of the neck as far as the level of the teeth and the length marked by a sliding mouthpiece (*F*); the tube is then introduced as far as indicated by the slider, and by blowing through the inner tube we ascertain whether the tube has just passed the cardiac opening, in which case the air no longer escapes upward through that opening. When the end of the tube has passed the cardiac opening I first blow a few times into the stomach so as to unfold it as much as possible; then I advance the tube about five or six centimetres, exactly the length of the perforated portion of the outer tube; the tube must depend free into the cavity of the stomach, surveying the field of operation, as it were.

The advantages are, briefly: 1. Constant pressure upon the fluid introduced. This pressure can be exactly regulated and interrupted when desired. The flow is not weakened at the end of the tube, since the latter is completely closed at the button. 2. All parts of the interior of the stomach are reached. 3. The fluid introduced is immediately removed by the return tube: in other words, the fluid which reaches the stomach in the form of spray always finds the organ empty; the stomach is not encumbered by a thick stream striking the wall; finally, there being an immediate escape of such chemical solutions as may have been introduced, there can be no intoxication by their passage through the pylorus into the intestine.

As an experiment, I may take one of my patients affected with chronic mucous inflammation of the gastric mucosa, introduce the ordinary tube so as to cleanse the stomach of mucus, etc., and the water, even in different positions of the patient, finally escapes perfectly clear. Then, introducing my douche, I am still able to remove additional tough mucus, and this I have repeatedly verified.

The effect of the stomach-douche is mechanical, chemical, and thermic. The mechanical effect is to be looked upon as a stimulus which produces a condition of excitation in nerve and muscle: by the force of the stream—an internal massage, as it were—we produce a direct and reflex stimulation of the vaso-motor nerves and thereby secondarily improve the circulation; the peristalsis is stimulated and the smooth muscle fibres respond more readily to tactile irritation. The agitation of the peripheral-nerve termini is propagated as far as the centres and transmitted by them to the motor fibres; a more intense oxidation of the blood within the muscle fibres is effected; sympathetic nerves and ganglia are directly stimulated; thus secretion and reflexes are produced in the organic muscular fibres and functional disturbances are overcome (Schreiber). In order to increase the stimulation of the muscular fibres I often employ an interrupted stream.

Thermic Effect.—By using warm water we secure the effect of a local bath; increased irritation of the sensory gastric nerves is reduced, reflex spastic contractures of the muscles are removed, and by the improved

circulation the vegetative processes in the wall of the stomach are favored. I intensify the thermic effect by the alternate production of warm and cold water. The stimulation of nerves and vessels by the action of cold is heightened by preceding heat.

Chemical Effect.—Malbranc used warm carbonated water (38° C.) and siphon. In these cases the carbonic acid acted as a local anodyne. For dissolving mucus we employ artificial Emser salt: chloride of sodium, 2 parts; carbonate of sodium, 1 part. For stimulating the secretion of hydrochloric acid we may use, not rarely with good results, table salt, one teaspoonful to the litre of water. Infusions of hops and quassia, cinchona bark, condurango bark, stimulate the muscles and motor nerves of the stomach, as well as the secretory nerves and those of the sensory nerves which transmit the sensation of hunger. Solutions of liquor ferri sesqui chloridi (½ to 1,000) have been used by me with striking results in anæmic and chlorotic patients. Nitrate of silver (½ to 2,000) was first used by Reichmann in gastrorrhœa for the purpose of reducing the secretion of hydrochloric acid. It will often relieve the symptoms of superacidity, though it does not cure that condition. In hyperæsthesias (the sensations being present when the stomach is empty, as opposed to gastric ulcer, in which the pain usually depends upon the presence of food) and erosions good symptomatic results have likewise been obtained with silver nitrate. The same may be said of hypersensibility (increase of hydrochloric acid need not necessarily cause symptoms). In gastrorrhœa the silver nitrate produces, aside from the amelioration of symptoms, a diminution of the hydrochloric acid, though not in every case (Rosenheim). Chloroform water (50 to 60 gm. of chloroform are agitated with one litre of water; the excess of chloroform sinks to the bottom of the vessel, and the supernatant water is drawn off for use), too, has been used with good effect in hypersensibility. In order to prevent intoxication from the use of silver nitrate solution or chloroform water, these liquids should not be left in the stomach for more than one-half to one minute, and the organ should then be washed out with warm water. Antiseptic effects are produced by solutions of salicylic acid (1 to 1,000).

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending September 14, 1895.

	Cases.	Deaths
Tuberculosis	95	114
Typhoid fever	31	8
Scarlet fever	20	1
Cerebro-spinal meningitis	4	4
Measles	60	4
Diphtheria	151	21

Birth of Child without Rupture of Membranes.—Dr. Forman observed this rare occurrence in the case of a woman aged twenty-two years, seven months advanced in her second pregnancy (*The British Medical Journal.*) She was suffering from pleuro-pneumonia, the temperature having risen to 103.6° F. A few minutes after cupping-glasses had been applied to the bases of the lungs the patient felt a desire to defecate; this was followed by a single pain which expelled the entire ovum with a little blood. There was no further escape of blood. Forman arrived a few minutes later. He found between the patient's thighs a big cyst with transparent walls. The mother was free from all the evils which may follow precipitate delivery; the uterus contracted well. The wall of the cyst was then cut; about a pint of amniotic fluid escaped. A female child was seen; there was no pulsation of the cord, but after active measures the infant breathed well and took the breast. It weighed 3 pounds 6 ounces, and measured over fourteen inches; the placenta weighed a little under a pound. The cord was very gelatinous, and measured eighteen and one-half inches in length. Judging from the position in which the ovum lay—outside the vulva—it seemed that the breech had presented, and that the placenta had been inserted very low down without being prævia. The child lived only sixteen hours, and the mother had a bad attack of empyema. Forman quotes a considerable number of cases of membranes unruptured at birth.

The Secretary of Agriculture on Rheumatism.—According to a newspaper interview Secretary Morton has improved upon the salicyl treatment of rheumatism, since he has discovered a means of prevention. He suffered with the disease, he said, for many years. One day, twelve years ago, someone told him that rheumatism generally followed kidney trouble, and that this disease was largely due to the starch in potatoes. Thereupon Mr. Morton stopped eating potatoes. He has eaten none in twelve years, and it is just that long since he has had a rheumatic twinge.

NEW BOOKS RECEIVED.

While the Medical Record *is pleased to receive all new publications which may be sent to it, and an acknowledgment will be promptly made of their receipt under this heading, it must be with the distinct understanding that its necessities are such that it cannot be considered under obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

SOME ORIGINAL INVESTIGATIONS, SHOWING THE ANTAGONISM BETWEEN MORPHINE AND COCAINE.[1]

BY JOSEPH WILLIAM STICKLER, M.S., M.D.,

ORANGE, N. J.

SOME time ago my attention was called to the apparent antidotal effect of opium in a case of cocaine intoxication. The patient in question had taken two ounces of a four per cent. solution of cocaine in about two hours. Being unable to sleep and being very nervous after having taken this large dose, he took about half an ounce of laudanum, which in the course of one hour relieved the nervousness and induced sleep. Except for some mental hebetude and a sense of muscular prostration, the patient was in fair condition all the next day—in good enough condition to attend to his business.

It seemed to me that such a result could only be explained by the antidotal effect of the laudanum. In order to determine whether my supposition was true I made some observations, the details of which, and the conclusions deduced therefrom, I respectfully ask you to consider. The observations were made on forty pigeons, two dogs, and four men, and in this work I was kindly assisted by Drs. William D. Arnold, Walter Dodge, and H. E. Matthews.

First Series.—Beginning at 11 A.M., October 12, 1894, I injected pigeons Nos. 1 and 2, with morphine, grain one-quarter. 11 A.M.: Pupils of pigeon No. 2 contracted, No. 1 unchanged. Both birds a little dull and unsteady. 11.13 A.M.: Pupils of pigeon No. 1 contracted. 11.15 A.M.: Pigeon No. 1 very unsteady. 11.22 A.M.: Gave pigeon No. 1 second dose of morphine, grain one quarter. 11.23 A.M.: Gave pigeon No. 2 second dose of morphine, grain one-quarter. 11.54 A.M.: Both birds quiet. Rather drowsy, but awake and susceptible to impressions. 12.07 P.M.: Gave No. 1 an injection of one-half grain of morphine, and at 12.10 P.M. gave No. 2 one-half grain of morphine; in a few moments both pigeons were drowsy and disinclined to move when approached. 2.29 P.M.: Injected into abdominal cavity of pigeon No. 1 two grains of cocaine, aqueous solution. 2.35 P.M.: Mild convulsions. Staggering gait. Head and neck thrown back, feet extended forward, tail and wings spread, pupils dilated. 3.06 P.M.: General condition much improved, makes efforts to walk, but is unable to properly co ordinate the muscles of locomotion. Respiration 80 and panting. 3.52 P.M.: Respiration is 52. Stands by bracing himself with wings and tail, keeps his bill open and sometimes makes a hissing sound during the respiratory act. Moves about on table from time to time, using his wings as supplementary helps. 5.45 P.M.: Died. 2.56 P.M.: Injected pigeon No. 2 with two grains of cocaine. The injection was made into the abdominal cavity. It flew about the laboratory as soon as released, and finally alighted upon one of the doors, where it rested quietly. 2.58 P.M.: When alarmed, lost its balance and flew to the floor. It could not stand. Developed convulsive movements. Head and neck drawn back. Bill open and respirations very rapid. Wings outspread, legs thrown directly back, and eyelids in constant motion. 3 P.M.: Head drooping. Respirations still rapid, and very shallow. Constant tremors. 3.02 P.M.: Gasping for breath. Breathing less rapidly. Eyes open and staring. Slight convulsive movements of neck. 3.02½ P.M.: Died. Morphine contracted pupils. Cocaine dilated them.

Second Series.—1.36 P.M.: Injected into abdominal cavity of pigeon No. 3 (no morphine having previously been given) two grains of cocaine. It became unconscious at once, and was placed in a basket. At 2.20 P.M., when I returned from lunch, he was dead. 2.32 P.M.: Injected into abdominal cavity of pigeon No. 4 (no morphine having previously been given) two grains of cocaine, and the bird was dead in less than sixty seconds. The syringe was scarcely emptied before the pigeon's head and neck were thrown back. Its wings outspread, and general convulsive movements developed, one or two gasps accompanied these manifestations, and life was extinct. Pupils of these birds dilated.

Third Series.—11.30 A.M.: Injected one grain of morphine subcutaneously into a dog weighing about six pounds. 12.18 P.M.: Dog lying down. Head stretched out and face evincing distress. Nausea and vomiting a few moments after injection. 12.25 P.M.: If touched, walks away from the place where he was lying, and after a while lies down again. 12.30 P.M.: Moves about voluntarily but has a staggering gait, and shows great weakness in his hind legs. 1.03 P.M.: Injected another grain of morphine. 1.12 P.M.: Rolled over on side and appeared very drowsy. Would get up and walk away when approached. 3.29 P.M.: Quite lively, trots across the room, but shows weakness in his hind legs. Injected one grain of cocaine into abdominal cavity. 3.32 P.M.: He soon began to run about the room, elevating each front foot as high as possible when in motion. Salivation constant and extreme. The urine flows freely. He suddenly fell upon right side, crying loudly. He next had convulsive movements. 3.34½ P.M.: Tonic convulsions. The front legs held out in front, stiff and straight. 3.36 P.M.: Quiet, and legs relaxed. 3.37 P.M.: Dead.

Dog No. 2 weighed about thirteen pounds. Injected at 11.30 A.M., into his abdominal cavity, one grain of morphine. He soon became nauseated and then vomited six times, after this he became quiet. 12.18 P.M.: Does not notice what is going on in the laboratory, or will not move if touched. Panting. 12.29 P.M.: Injected one grain of morphine. 12.58 P.M.: Rolls over on his side but regains his position. 1.35 P.M.: Injected two grains of morphine. 2.48 P.M.: Hind legs paralyzed. Very quiet. 2.59 P.M.: Injected two grains of cocaine. 3.13 P.M.: Injected two grains of cocaine. Almost immediately tongue was protruded from mouth. Profuse and constant discharge of saliva, and urine ran freely and steadily for some time. During this time he lay on the floor with his legs extended, and a wild expression of face. Head drawn to right side. 3.30 P.M.: Salivation still more decided. 3.48 P.M.: Injected two grains of cocaine. 3.55 P.M.: Head rolls from side to side. 3.56½ P.M.: rolls over on side. Head drawn

[1] Read before the Medical Society of New Jersey at its last annual session at Cape May, June 25, 1895.

back. Front legs stretched out. Hind legs drawn up. 4.03 P.M.: Tonic convulsions. 4.10 P.M.: Convulsions cease. Looks quite natural, tries to get up and walk, but cannot, as hind legs are still paralyzed. Moves about by reaching forward with his front legs and dragging his body. Sometimes moves rapidly in a circle. 4.18 P.M.: Had another convulsion, but not as severe as the other. 4.20 P.M.: Appears brightly. 4.30 P.M.: Throws body on hind legs and then revolves rapidly. Sight seems impaired, as he often hits his head against various things in the laboratory. 4.40 P.M.: Making rapid revolutions, using hind legs as pivotal points. 4.45 P.M.: Seems to be resting. 4.55 P.M.: Very lively. More strength in hind legs, occasionally rises on them. 5 P.M.: Salivation and urination have ceased. Seems to act like a dog scared at something, and would make violent efforts to get away.

After 5 o'clock P.M., Dr. Walter Dodge watched this interesting specimen of the canine species, and his experience with him was a somewhat lively one. At times he would remain perfectly quiet, then he would make a few trips around the laboratory at a rate of speed that would astonish a streak of chain lightning, and he was not over-particular what he "took in" on the way. On one of his rounds he put his head into a cuspidore, and with that as a helmet, he whizzed around the laboratory about twenty times. Then again he got tangled up with the blackboard frame, and with that on his back, he went around the laboratory table at the rate of about one hundred and fifty times to the minute. The doctor, thinking that it would be wise to get out of the way of this active animal, perched himself upon a high stool and placed three or four chairs in front of it as a protection. Thus barricaded he felt comparatively secure. The dog, however, ran under the chairs and got under the stool on which the observer was standing, and by means of a tremendous effort upset stool and doctor, the latter coming down on the dog, a result he evidently was not looking for, as he gave a howl and "lit out" at a rate that assured the doctor that, whatever paralysis he had suffered from a comparatively short time before, had entirely disappeared. Part of the time he was entertaining Dr. Dodge in the manner stated and part of the time he was quiet. The following morning he was perfectly normal, except that he looked disgusted with everything that reminded him of his experiences of the day before; he was therefore given his freedom.

Fourth Series.—Injected into abdominal cavity of pigeon No. 5, two grains of morphine at 10.35 A.M., June 7, 1895. 10.40 A.M.: Dull, and shows some lack of co-ordinating power on attempting to walk. 10.55 A.M.: Disposed to be quiet, but can fly when thrown into the air. 11.04 A.M.: Injected two grains of cocaine into abdominal cavity. 11.06 A.M.: Toppling backward and forward. Bill open and respiration somewhat quickened. Wings partly spread. 11.13½ A.M.: On side. Tail spread and wings extended. 11.37 A.M.: Dead.

Injected into pigeon No. 6 two grains of morphine at 10.38 A.M. 10.42 A.M.: Drooping. Winking rapidly and totters when he walks. Pupils contracted. Respiration slow. 10.55 A.M.: Can fly well. General condition good. 11.10 A.M.: Injected two grains of cocaine into abdominal cavity. 11.12 A.M.: Wings outstretched. Legs extended backward. Bill open. Pupils dilated. 11.17 A.M.: Dead.

Injected into pigeon No. 7 two grains of morphine at 10.45 A.M. 10.50½ A.M.: Drowsy and staggering. 10.55 A.M.: Can fly. 11.02 A.M.: Tilted forward on chest, but can walk and fly. Pupils contracted. 11.19 A.M.: Injected two grains of cocaine into abdominal cavity. 11.21 A.M.: Fluttering about. 11.23 A.M.: Dead.

Injected into pigeon No. 8 two grains of morphine at 10.47 A.M. 10.50 A.M.: Drowsy and a staggering gait. Pupils contracted. 10.55 A.M.: When thrown into the air, can fly well. 11.02 A.M.: Tilted forward on chest, but is strong enough to walk and fly. 11.19 A.M.: Injected into abdominal cavity two grains of cocaine. 11.21 A.M.: Convulsive movements. 11.23 A.M.: Dead.

Fifth Series.—Injected into abdominal cavity of pigeon No. 9 one grain of morphine at 10.15 A.M., June 7, 1895. Pigeon almost immediately became quiet, but not sleepy. Pupils contracted. 11.24 A.M.: Injected one-half grain of cocaine into abdominal cavity. 11.26 A.M.: General convulsive movements. Tail and wings spread. 11.37½ A.M.: Dead.

Injected into abdominal cavity of pigeon No. 10 one grain of morphine at 10.56 A.M. Pigeon became quiet in a few moments, but was easily aroused. Pupils contracted. 11.26 A.M.: Injected one-half grain of cocaine into abdominal cavity. 11.28 A.M.: Head thrown back, wings outstretched. Pupils dilated. 11.35 A.M.: Dead.

Injected into pigeon No. 11 one grain of morphine at 10.57 A.M. 11.29 A.M.: Injected one-half grain of cocaine into abdominal cavity. 11.35 A.M.: Convulsions. Injected one-half grain of morphine into abdominal cavity. Bird became quiet and conscious. Breathed easily and remained quiet until 12.11 P.M., when it died.

Injected into abdominal cavity of pigeon No. 12 one grain of morphine at 10.58 A.M. Became quiet and sleepy in a short time. Pupils contracted. 11.31½ A.M.: Injected into abdominal cavity one-half grain of cocaine. The pigeon soon began to totter, but remained upon its feet until 11.40½ A.M., when it died.

Sixth Series.—Injected into abdominal cavity of pigeon No. 13, at 2.33 P.M., June 7, 1895, one-half grain of atropine. At 2.41 P.M. injected into abdominal cavity one-half grain of cocaine. Pigeon lived.

Injected into pigeon No. 14 one-half grain of atropine. Five minutes later injected one-half grain of cocaine. Pigeon died in fifty seconds.

Injected into abdominal cavity of pigeon No. 15 one-half grain of atropine at 2.46 P.M. 3.50 P.M.: Injected one-half grain of cocaine. Pigeon died in seven minutes.

Injected into pigeon No. 16 one-half grain of atropine at 3.47 P.M. Later injected one-half grain of cocaine. Pigeon died in sixty seconds.

Seventh Series.—Injected into abdominal cavity of pigeon No. 17 one-half grain of atropine at 12.32 P.M., June 8, 1895. 12.09 P.M.: Nauseated. 12.39 P.M.: Injected one grain of cocaine into abdominal cavity, and pigeon died in twenty seconds.

Injected into pigeon No. 18 one-half grain of atropine at 12.04 P.M. 12.09 P.M.: Nauseated. 12.32 P.M.: Injected into abdominal cavity one grain of cocaine. Pigeon died in five minutes.

Injected into abdominal cavity of pigeon No. 19 one-half grain of atropine at 12.05 P.M. Nauseated a little later. 12.29 P.M.: Injected into abdominal cavity one grain of cocaine. Pigeon died in seventeen seconds.

Injected into abdominal cavity of pigeon No. 20 one-half grain of atropine at 12.07 P.M. Nauseated a few moments later. 12.26 P.M.: Injected into abdominal cavity one grain of cocaine Pigeon died in fifteen seconds.

Eighth Series.—Injected into abdominal cavity of pigeon No. 21 one grain of morphine at 11 A.M., June 8, 1895. 11.28 A.M.: Manifestly stupid. 11.59 A.M.: Injected three-quarters of a grain of morphine. Half an hour later very stupid. Pupils contracted. 1.14 P.M.: Injected one grain of cocaine into abdominal cavity. 1.23 P.M.: Pigeon dead.

Injected into abdominal cavity of pigeon No. 22 one grain of morphine at 11.22 A.M. 11.28 A.M.: Quite willing to sit still. 11.56 A.M.: Injected one grain of morphine. 1.24 P.M.: Injected one grain of cocaine into abdominal cavity. 1.27 P.M.: Totters about when walking. 1.28 P.M.: General convulsive movements. 2.05 P.M.: Pigeon dead.

Injected into abdominal cavity of pigeon No. 23 one grain of morphine at 11.05 A.M. 11.28 A.M.: Disposed to be quiet. 11.43 A.M.: Injected one grain of morphine. The second dose made the pigeon very quiet. 1.18 P.M.: Injected into abdominal cavity one grain of cocaine. 1.22 P.M.: Pigeon dead.

Injected into abdominal cavity of pigeon No. 24, one grain of morphine at 11.07 A.M. 11.15 A.M.: Rather stupid and tottering. Pupils contracted. 11.28 A.M.: Very quiet. 11.45 A.M.: Injected one grain of morphine. 12.48 P.M.: Injected into abdominal cavity one grain of cocaine. 12.51 P.M.: Tottering gait. Pupils dilated. Quiet. 12.56 P.M.: Marked convulsive movements. 1.20 P.M.: Pigeon dead.

Ninth Series.—Injected one-quarter of a grain of cocaine into abdominal cavity of pigeon No 25 at 12.10 P.M. 12.12 P.M.: Pupils widely dilated. Tail spread. Gait tottering. 12.14 P.M.: Fell down. Staggers about. 12.15 P.M.: On back. Head thrown back. Bill open. Respiration rapid and labored. 1.22 P.M.: Active convulsions. Eyes closed. Wings and tail spread. Unable to stand or fly. 1.40 P.M.: Standing and apparently recovering. Can use wings. 1.50 P.M.: Suddenly fell forward. Gasped once or twice, and then died.

Injected into abdominal cavity of pigeon No. 26 one-quarter grain of cocaine at 12.15 P.M. 12.18 P.M.: Unsteady. 12.23 P.M.: Vomiting, and except slight shiverings, showed no effects of the drug.

Injected into pigeon No. 27 one-quarter grain of cocaine at 12.18 P.M. 12.27 P.M.: Pigeon on back with wings extended. Pupils dilated. 12.29 P.M.: Pigeon dead.

Injected into abdominal cavity of pigeon No. 28, one-quarter grain of cocaine at 12.21 P.M. Paralyzed almost immediately. 12.24 P.M.: Completely prostrated. Respiration is very rapid and panting. 12.25 P.M.: Dead.

Tenth Series.—Injected into abdominal cavity of pigeon No. 29 one grain of morphine at 11.09 A.M. 11.28 A.M.: Disposed to be quiet. 11.39 A.M.: Injected one grain of morphine into abdominal cavity. 12.41 P.M.: Injected one-quarter grain of cocaine into abdominal cavity. 12.43 P.M.: Convulsive movements. 12.48 P.M.: Dead.

Injected into abdominal cavity of pigeon No. 30, one grain of morphine at 11.10 A.M. 11.28 A.M.: Quiet, but easily aroused. 11.35 A.M.: Injected one grain of morphine. 12 M.: Injected one-quarter grain of cocaine. 1.30 P.M.: Gait tottering. 1.44 P.M.: Dead.

Injected into abdominal cavity of pigeon No. 31 one grain of morphine at 11.12 A.M. 11.16 A.M.: Vomited. 11.28 A.M.: Resting quietly. 11.47 A.M.: Injected one grain of morphine. Bird became quiet in a few moments. 12.43 P.M.: Injected into abdominal cavity one-quarter grain of cocaine. 12.51 P.M.: Gait tottering. Bill open. Pupils dilated. 1.40 P.M.: Can fly and is quite natural in appearance. This pigeon made a good recovery.

Injected into pigeon No. 32 one grain of morphine at 11.13 A.M. 11.28 A.M.: Sitting quietly on floor. Easily disturbed. 11.52 A.M.: Injected one grain of morphine. 12.46 P.M.: Injected one-quarter grain of cocaine into abdominal cavity. 12.51 P.M.: Tottering gait, and pupils dilated. 1.40 P.M.: Pigeon can fly and is rapidly becoming normal. Made a good recovery.

Eleventh Series.—Injected into abdominal cavity of pigeon No. 33 one-half grain of cocaine. Pigeon died in thirty seconds.

Injected into pigeon No. 34 one-half grain of cocaine. Died in sixty seconds.

Injected pigeon No. 35 with one-half grain of cocaine. Died in twenty seconds.

Injected pigeon No. 36 with one-half grain of cocaine, lived three minutes. In each instance, the pupils were dilated.

Twelfth Series.—Injected pigeon No. 37 with two grains of cocaine subcutaneously. Died in sixty seconds. This bird stood perfectly still a few moments after injection, then suddenly died. Pupils dilated.

Injected subcutaneously pigeon No. 38 with two grains of cocaine at 11 A.M. In a very short time convulsions developed. I then injected into abdominal cavity one grain of morphine, convulsions ceased, bird became quiet, and died at 12.14 P.M.

Injected into abdominal cavity of pigeon No. 39 one grain of morphine and one grain of cocaine. Pigeon died in two minutes.

Injected into pigeon No. 40 one grain of morphine and one-half grain of cocaine. Pigeon lived one minute.

The following observations were made in the presence and with the assistance of Drs. George Bayles, Thomas P. Fitch, Mefford Runyon, and H. E. Matthews. In these cases I gave only the same quantity of morphine and cocaine that I administered in private practice. My wish was to demonstrate to others what I had already witnessed.

Thirteenth Series.—Mr. E——, aged thirty-eight, lungs, heart, kidneys, and other organs in good condition. Skin warm and dry. Before administration of cocaine, pulse 66. Respirations, 24. Temperature, 98⅘° F. 7.58 P.M., October 12, 1894: Patient took one grain of cocaine (in aqueous solution) into mouth and held it there five minutes, then swallowed it. His pupils began to dilate four minutes later. Pulse, 72: respirations, 28. Sialogogue effect pronounced in five minutes. 8.08 P.M.: Patient felt elated. Hands moist. 8.12 P.M.: Pulse, 68; respiration, 20. Pupils quite widely dilated. 8.14 P.M.: Mental exhilaration not quite so pronounced. But said that the sense of muscular fatigue he had when he came to the laboratory had all disappeared, and he felt as if he could walk to Newark and back. 8.21 P.M.: Pulse, 72; respirations, 20; temperature, 98½° F. 8.31 P.M.: Palms of hands moist, otherwise condition the same. 8.39 P.M.: Gave hypodermic injection of morphine, grain one-quarter, in forearm. 8.45 P.M.: Pulse, 80; respirations, 20. Feels a little heavy. Pupils very slightly contracted. 8.50 P.M.: Pulse, 72; respirations, 20. Palms still moist. Did not complain of dry throat or mouth. Pupils somewhat more contracted than at time of previous observation. Feels slight muscular fatigue. No nausea. 9.01 P.M.: Respirations, 20; pulse, 78, strong and regular. 9.05 P.M.: Temperature, 98½° F. Not at all sleepy or inclined to lie down or keep quiet. Rather talkative. This patient went to his home about one mile distant, and had a comfortable night, except that he was wakeful until three or four o'clock the next morning.

Mr. E. B——, aged twenty-one, in perfect health. Prior to administration of cocaine, pulse, 66; respirations, 24; temperature, 98⅘° F. Skin warm and dry. 7.58 P.M.: Took one grain of cocaine in aqueous solution into his mouth, retained it there five minutes, then swallowed it. 8.01 P.M.: Pupils dilated. 8.05 P.M.: Pulse, 80, regular and strong; respirations, 28. Pupils quite widely dilated. Sialogogue effect pronounced. 8.10 P.M.: Pulse, 76; respirations, 26; pupils, same. 8.15 P.M.: Feels elated and inclined to use his muscular system. 8.21 P.M.: Temperature, 99⅕° F. 8.30 P.M.: Pulse, 74; respiration, 22; temperature, 99° F. Pupils a little less dilated than before. 8.39 P.M.: Hypodermic injection of morphine, grain one-quarter into forearm. 8.45 P.M.: Says he feels comfortably, "just a little heavy," but not inclined to sleep or lie down. 8.52 P.M.: Pulse, 72; respirations, 20. Palms still moist, and does not complain of dry mouth or throat. 9.05 P.M.: Temperature, 98⅘° F. Feels perfectly fresh and wide awake. 9.11 P.M.: Pupils normal. No nausea or headache. He walked about one mile to his home, and with the exception of some wakefulness had a comfortable night.

Fourteenth Series.—Mr. J. B——, aged seventeen. In perfect health. Prior to hypodermic injection of morphine, pulse, 80 ; respirations, 18 ; temperature, 97⅘° F. Skin slightly cool. Face warm. Pupils quite widely dilated. 7.43 P.M. : Administered hypodermically in forearm one-fourth grain of morphine. 7.49 P.M. : Pulse, 80, full and strong. 7.52 P.M. : A slight dizziness, and in five minutes later, pulse 88. 8.09 P.M. : Pulse, 80 ; respirations, 18. 8.14 P.M. : Pulse, 80. Pupils remarkably contracted and patient decidedly sleepy. Face pale, and skin cool and dry. 8.22 P.M. : Says, legs are tired. Pulse, 80, and thready ; respirations, 16. Patient manifestly sleepy. 8.25 P.M. : Gave patient one grain of cocaine by mouth. He retained it there five minutes before swallowing it. 8.35 P.M. : Pulse, 80 and strong ; respirations, 18. Pupils slowly expanding. 8.38 P.M. : Feels nauseated. 8.40 P.M. : Still feels sleepy. 8.45 P.M. : Not so sleepy. Nausea disappeared. Walks about. 8.48 P.M. : Pulse, 68 ; normal in character ; respirations, 18. Pupils dilated. 8.55 P.M. : Pulse, 72 ; respirations, 20. 9 P.M. : Vomited. 9.02 P.M. : Feels brighter. This man drove home, a distance of two miles. He was somewhat wakeful during the night.

Mr. B——, aged fifty. Except for a slight cold, was well. Prior to subcutaneous injection of morphine, pulse, 90 ; respirations, 20 ; temperature, 99⅘° F. Pupils normal. 7.42 P.M. : Injected into forearm one-fourth grain of morphine. 7.50 P.M. : Pulse, 84. Otherwise no change. 7.55 P.M. : Pulse, 88. 8. P.M. : Pulse, 84, fuller and stronger. 8.07 P.M. Pulse, 72 ; respirations, 20. 8.12 P.M. : Pulse, 80. Pupils remarkably contracted. 8.18 P.M. : Said he felt muscular weakness. Was quite drowsy. Pulse, 66 ; respiration, 22. 8.25 P.M. : Patient took into his mouth one grain of cocaine, held it there five minutes, then swallowed it. 8.35 P.M. : Pulse, 72 and stronger ; respirations, 22. Pupils still contracted. Not so tired or sleepy. 8.40 P.M. : Pulse, 74 and strong ; respirations, 18. 8.45 P.M. : Feels as well as ever. Pulse, 72 ; respirations, 18. He walked some distance to get his horse and wagon, and then drove home.

At this point I may say, that the above results are in harmony with those I have obtained in the treatment of patients in private practice. I have also witnessed the following effects of cocaine : 1. Lengthening of respiratory act. Ten seconds frequently being consumed before the process was completed. 2. Expiration was sometimes lengthened to such an extent as to occupy ten or fifteen seconds of time. 3. The entire muscular system energized and stimulated so that the patient could walk or work a long time without fatigue, however tired before the administration of the drug. 4. Intellectual faculties revived and sustained in active operation a long time. 5. Wakefulness of a temporary character, if the cocaine were given in small doses and for a brief time. Insomnia of a more or less permanent type if the drug were continued any length of time. 6. Decided impairment of appetite. 7. Most marked and prompt stimulation of sweat glands, salivary glands, and kidneys. 8. Involuntary flow of urine when dose is excessive. 9. Great prostration following withdrawal after prolonged or excessive use. 10. First quickening, then slowing, of respiration. 11. Pulse somewhat quickened and strengthened.

Remarks and Deductions.—The following remarks apply only to pigeons : 1. They are extremely susceptible to cocaine. One-half grain will almost always kill in a few seconds. One-quarter of a grain is usually fatal in a few moments. 2. One grain or more of cocaine is always fatal in a few seconds or minutes. 3. Its administration is always followed by convulsive movements, if a toxic dose be given. 4. It invariably quickens respiration and renders it gasping and shallow, when a lethal dose has been given. 5. It always dilates the pupils, and makes the heart beat more rapidly and forcibly if a medical dose be administered. 6. It causes a staggering gait when given in excess. 7. When a non-toxic dose is administered, nausea and vomiting follow, then some tremors which last a short time, and the bird appears quite natural. 8. When injected subcutaneously its characteristic effect is somewhat delayed, but it finally obtains. 9. When injected into abdominal cavity it acts almost instantly. The difference in time between the two methods is only a few moments. 10. The average time pigeons lived after intra-abdominal injections of two grains of cocaine, one grain of morphine having been previously administered, was $2\frac{8}{10}$ minutes. 11. Average time pigeons lived after intra-abdominal injections of two grains of cocaine, two grains of morphine having previously been given, $11\frac{3}{10}$ minutes. 12. Average time pigeons lived, injected with one-half grain of cocaine (intra-abdominal), previously treated with one grain of morphine, was fifteen minutes eight seconds. 13. Average duration of life of pigeons into whose abdominal cavities one-half grain of cocaine has been injected, previously treated with one-half grain of atropine, was two minutes eight seconds. 14. Average time pigeons lived after injection of one grain of cocaine into abdominal cavity, half-grain of atropine having previously been given, was one minute thirty-eight seconds. 15. Average time pigeons lived after injection of one grain of cocaine into abdominal cavity, two grains of morphine having previously been given, was twenty-five minutes six seconds. 16. Pigeons treated with three-quarters of a grain of morphine, then with one grain of cocaine, lived nine minutes. 17. Pigeons into whose abdominal cavities one quarter of a grain of cocaine was injected, no morphine having previously been given, lived thirty eight minutes thirty-two seconds. 18. Pigeons treated with two grains of morphine (injected into abdominal cavity), then with one-quarter of a grain of cocaine, lived on an average of fifty-five minutes fifty-five seconds. 19 Pigeons into whose abdominal cavities one-half grain of cocaine was injected had an average life of only one minute two seconds. 20. Two grains of cocaine injected subcutaneously, killed in sixty seconds. 21. One grain of morphine and one grain of cocaine injected into abdominal cavity of pigeon caused death at the end of two minutes. 22. Pigeons injected with two grains of cocaine subcutaneously, then with one grain of morphine, lived one hour and five minutes.

I wish now to institute, if possible, a striking comparison of results, which will make clear the point these investigations are intended to prove.

First, in relation to the pigeons. Taking into account all the birds treated. Those having first morphine, then a lethal dose of cocaine, had an average life of forty-four minutes and eight seconds. Those having first atropine, then a lethal dose of cocaine, had an average life of one minute and forty-two seconds. Those having only a lethal dose of cocaine had an average life of one minute and two seconds.

This comparison shows conclusively, so far as pigeons are concerned, that morphine and cocaine are manifestly antagonistic to each other. It further shows that atropine furnishes almost no protection (probably none) against the prompt and violent action of cocaine.

As far as the dogs are concerned, it would seem that while two grains of morphine do not successfully antagonize one grain of cocaine, four grains of morphine will serve as an antidote for four grains of cocaine.

A comparison of results furnished by the investigations upon the man, clearly shows the mutual antagonism between the two drugs. Morphine contracted the pupils. Cocaine dilated them. Morphine retarded pulse-rate somewhat, but did not alter its force perceptibly. Cocaine accelerated the pulse and strengthened it. Morphine diminished the number of respirations to the minute. Respirations were in-

creased in number by cocaine. (When any considerable quantity of cocaine is taken, respirations are cut down in number and altered in character, as already indicated.) The morphine produced a sense of muscular fatigue and drowsiness. Cocaine energized and made active the muscular system and had a "waking-up effect" upon the intellectual faculties. Morphine caused dryness of throat, mouth, and skin, also impaired functional activity of kidneys. Cocaine increased the moisture of the throat, mouth, and skin, and increased the functional activity of the kidneys.

Thus it is seen that those two agents are opposed to each other in their therapeutic action upon man. I have given to patients who have had severe pain, one-fourth grain of morphine and one-fourth grain of cocaine hypodermically, and not only has the pain been relieved, but there has been no drowsiness, nausea, or vomiting to interfere with attention to the business of the day. When morphine is to be given at night in comparatively small doses, it is best not to use cocaine, as it is likely to prevent sleep, so decided is it in its effect upon the brain.

The very rapid diffusibility of cocaine has been made prominent in these investigations. When given hypodermically, a constitutional effect of the most decided character was produced in a little less than fifteen seconds. Even when held in the mouth in a small quantity, a constitutional effect was produced in two minutes by local absorption. In this short time there was some dilatation of the pupils and a beginning sense of muscular and mental exhilaration. Diaphoresis was also experienced.

At this point let me quote a case which is an additional demonstration of the value of cocaine as an antidote for opium.

Dr. H. E. Matthews, my associate in laboratory work, was called to treat a case of opium poisoning. Being interested in my investigations, he concluded to use cocaine as an antidote. The details of his experience are as follows:

Mrs. R——, on June 6, 1895, about 6.45 P.M., during a quarrel with her husband, took a three-ounce bottle of laudanum which was nearly full, and drank all but about half an ounce of its contents. When Dr. Matthews saw her, twenty minutes later, her pupils were contracted and she was greatly excited; so greatly excited that he considered her respirations, 16 to the minute, due in a large measure to the nervous disturbance. Her pulse was 80. He gave her six grains of hydrarg. sulph. flava, which in five minutes made her vomit a clear fluid which had neither the color nor odor of laudanum. He concluded, therefore, that most of the poison had been absorbed. He then administered hypodermically one-half grain of cocaine. At 7.40 P.M., she was more quiet in manner, but felt more vigorous. He then gave her hypodermically one-quarter grain of cocaine. In one hour she was perfectly normal and in her general condition, her pupils being well dilated.

I doubt if permanganate of potash or atropine would have given as good a showing as that.

In conclusion, let me say that in any case of opium poisoning, I would first employ an emetic, then I would give hypodermically one-fourth to one-half grain of cocaine; wait twenty minutes, and if no decided effect had been obtained I would give another injection of one-fourth grain; after waiting another twenty minutes I would repeat the dose if there were no manifest improvements in the case. I think three separate doses of one-quarter grain each at intervals of twenty minutes, is the best plan to follow, on account of the very quick diffusibility of the drug and its sustained effect. During this time I would administer coffee by mouth or rectum as a supplementary heart stimulant, and in extreme cases employ artificial respiration.

While I urge this method, I hope with becoming deference to the opinion of others, concerning other plans of treatment, I urge it with the honest conviction that it is an improvement upon the atropine and permanganate of potash methods.

NUCLEIN IS NATURE'S ANTITOXIN, AND SOME OF THE FUNDAMENTAL PRINCIPLES UNDERLYING OUR MODERN THERAPY.[1]

By J. MOUNT BLEYER, M.D., F.R.A.M.S. NAPLES.

NEW YORK CITY.

LARYNGOLOGIST TO THE GERMAN WEST-SIDE CLINIC; MEMBER OF THE MEXICAN NATIONAL ACADEMY OF MEDICINE; MEMBER OF THE OTOLOGICAL AND LARYNGOLOGICAL SOCIETY OF PARIS, FRANCE; MEMBER OF THE FRENCH SOCIETY OF ELECTRO-THERAPEUTICS; MEMBER OF THE AMERICAN MEDICAL ASSOCIATION, MEMBER PEDRO-ESCOHEDO, MEXICO, ETC.

A LITTLE over five decades have just crept by us since the great Schwann communicated the results of his discoveries on animal tissues to the French Academy, which became the foundation to a budding science upon which since then an imposing structure has been built.

Closely following upon Robert Brown's and Schleiden's work, Schwann published, in 1839, his famous microscopical researches, and came to the conclusion that all possible tissues of both animals and plants consisted of cells, or of materials derived from cells, it seemed that the primary units—molecules, so to say, of which all living beings are built up, had finally been discovered. A small piece of structureless, granulated, jelly-like substance—the sarcode in animals and the protoplasm in plants—surrounded or not by a thin membrane, and containing a nucleus, this was the primary unit, giving origin to all the most complex and varied tissues.

This conception gave a formidable impulse to science and to scientific philosophy altogether, the more so as it was soon followed by a most important discovery which established the close resemblance existing between the subdivision of cells and the phenomena of sexual reproduction in plants and animals. Twenty-two years later, another still more important step was made in the same direction when Max Schultz published his memoir "Das Protoplasm," and proved that the granular, jelly-like substance of the cells is identical in both the animal and vegetable kingdoms, that it is the very seat of all physiological activity, as it is capable of movement, of nutrition, of growth, of reproduction, and even of sensibility, or, at least, of irritability. Many must certainly remember the effect produced by the broad generalization based upon Max Schultz's ideas by Haeckel in Germany, and Mr. Huxley in his well-known lay sermon, "The Physical Basis of Life."

However, if protoplasm were the seat of physiological activity; if it could move, grow, reproduce itself, and display irritability, was it still to be considered as a structureless, granulated jelly or slime? It was a world in itself, and the microscope had to be directed toward the further study of this world. So it was, by Lionel Beale, Schultz himself, Strasburger, and most of the famous histologists. Discovery upon discovery was the reward of this work, and the recent researches of Strasburger, Fleming, Guignard, and Fol, while fully confirming the broad generalization laid at the foundation of modern biology, revealed a wide series of new facts having a direct bearing upon the question of heredity which is so much debated now in connection with Weismann's views.[2]

[1] Read before the American Medical Association, May 7, 8, 9, and 10, 1895. Section, Practice of Medicine.

[2] Strasburger: Ueber Kern-und Zell-Theilung in Pflanzenreiche, Jena, 1888; Guignard, in Bull. Soc. Botanique de France, 1890, tome xxxvi., and Comptes Rendus, 1891, tome cxii., pp. 539, 1074, and 1320; tome cxiii., p. 917; W. Fleming, in Archiv für Mikrosk Anatomie, 1891, Bd. xxxvii., p. 249, and Anatomischer Anzeiger, 1891, p. 78. An immense literature has suddenly grown up upon this subject; excellent

From the above-mentioned researches it became evident that protoplasm itself consists at least of two different substances—one of them a minute net-work of very delicate fibrils, while the other, an apparently homogeneous substance, filling up the interstices between the net-work. Then it was observed that the nucleus, which makes a necessary constituent part of cells, has a still more complicated structure of subdivision of the cells, and those of reproduction. It consists of a nuclear plasm, surrounded by a very thin membrane; contains very often a still smaller nucleolus; and within the nuclear plasm the microscope discovers extremely thin threads, or fibres, consisting in their turn of extremely thin minute granules, or sporules—the whole appearing as a ball of thread coiled up somewhat roughly. The albuminous matter of which these threads consist receive the name of "Nuclein," and the threads themselves were named chromatin fibres, owing to their affinity for coloring matter. The transformation in the nucleus which has just been described received the general name of Karyokinesis, or nuclear movement. (The names, as seen, are simply descriptive.) This being the usual aspect of the nucleus, a series of modifications begin within it, when the moment arrives for a cell to subdivide. The nucleolus disappears; the beaded threads, or fibres, shorten and become thicker. They assume the shape of minute hooks, which join together (by the tops of the bendings) in one point, the pole. By the same time the membrane of the nucleus is reabsorbed, and the surrounding protoplasm of the cell penetrates within the nucleus, thus mixing up together with the nuclear plasm. Thereupon a most important change follows. Each of the thickened nuclein fibres, or threads, splits in its length, and the number of the threads being thus doubled, one-half of them is attracted toward a radiated spindle-figure in one part of the cell, while the other half arranges in the same way in its opposite part. The two radiated figures thus separate, and only then (if the nucleus subdivides in giving origin to two new cells) a membrane, or parts of a membrane, grow between the two. After the separation, the fibres either coalesce with their ends or return to the shape of a ball of thread.

It is a whole world undergoing a complete cycle of modifications. And yet this is not all. It appears from Strasburger's work that all the cells are not quite alike, but that the number of nuclein fibres varies from eight to sixteen in the different families of plants, the individuality of the types thus seemingly depending upon their number; while Guignard found that with several plants the cells which will be destined, after the division of the mother-cell, to become the reproductive organs, will always have but one-half of the normal number of fibres (say twelve), while those which are destined to become the vegetative organs will have the full number — say twenty-four.[1] The former will acquire the full number of fibres only after fecundation. Are, then, the cells differentiated from the first movement of their bi-partition? And what part does the number of chromatine fibres play in that differentiation?

Further complications are discovered through the study of the protoplasm itself. It was known some time ago that there are, in the animal cells, two peculiar spots surrounded by rays of sarcode, which were named spheres of attraction, or directing spheres, or centrosomata, or simply "centres." The same minute centres have now been found by Strasburger and Guignard in vegetable cells also, and it appears that these bodies essentially belong to the protoplasm—not to the nucleus—take a leading part in the phenomena of reproduction. Professor Fol, who carried on his researches with eggs of sea-urchins, saw that when the elements of the male cell have entered the female cell, the centre of the former separates from the top of its nucleus and joins the centre of the latter. Both lie close to one another; then they become elongated and take positions on the opposite sides of the nucleus, which is now formed by both coalesced nuclei, surrounded by a radiation of the fibrils of protoplasm. Then begins what Fol terms the "quadrille of the centres." Each of them divides into two half-centres, and all four move, so that each half-centre of the male cell meets and coalesces with one half-centre of the female cell, and the two newly formed centres become the poles of attraction for the spindles of the nucleus. The act of fecundation is thus not a simple coalescence of two nuclei, originated from two separate individuals, as was first supposed; but it also consists of the union of each two of the four half centres originated in the protoplasm.

The interest attached to these minute changes is great, on account of their influence upon the theory of heredity. The observations of Fol, and the quite analogous observation of Guignard as regards plants, would only confirm the doubts expressed by Sir William Turner in his address before the Microscopical Society[1] as to the germ plasm being so isolated from the cells of the body generally as to be influenced by them and to be unaffected by its surroundings; and they would give further weight to his restrictions upon Weissmann's theory of heredity. However, the questions at issue are so complicated and so delicate that further research is necessary before positive conclusions can be drawn.

But what is protoplasm itself? What is this jelly-like matter which exhibits all phenomena of life? Science has not yet given an absolute answer to this great question. On the one side, we have the germs of an opinion, shared by some biologists who are inclined to see in protoplasm an aggregation of lower organisms. Thus R. Altmann[2] and I. Strauss[3] consider that the granulations of protoplasm are the essential and fundamental elements of the organic being. As to the cell, it is not, in Altmann's opinion, an elementary organism, but a colony of elementary organisms which group together, according to certain fixed rules of colonization. They constitute the protoplasm as well as the nuclear plasm, and they are the morphological units of all living matter. These granules, he maintains, are identical with microbes; their shape, their chemical reaction, their movements, and their secretory functions are similar; but the granules of the protoplasm differ from bacteria in not being capable of a separate existence. They can only live in cells. It is absolutely impossible to say, at the present time, how far this view may find indorsement in later research, though it must be mentioned that it is derived from elaborate investigations into the cells of various glands and their secretions, and that it finds support in facts accumulated by many well-known anatomists.[4] It must also be added that some biologists, namely, J. C. Vogt,[5] go a step further and maintain that all micro-organisms, and all cells of more complicated organisms are structures of a fourth or higher order; they are colonies of polyblasts, which themselves consist of monoblasts, or those granules which are distinguished in the protoplasm and the nuclear plasm. But, on the other side, we also have the other extreme view, supported by the authority of

[1] *A summary* of the whole question have been given in English up to 1888 by Professor McKendrick, in Proceed. Glasgow Philos. Society, vol. xix.; and to the end of 1890 by William Turner in an address, The Cell Theory, Past and Present, delivered in October, 1890, before the Scottish Microscopical Society (Nature, vol. xiv., p. 2 et seq.).

Professor O. Bütschli, who sees in protoplasm nothing but a foam, quite similar to the foams which may be artificially produced, and who maintains that all phenomena observed in living protoplasm are simply physical and chemical processes.

The great question as to what protoplasm is, evidently will not be solved soon, but the above-mentioned researches will give an idea of the problems which at this moment absorb the attention of biologists. One important step has certainly been made, the complicated structure of protoplasm has been recognized and the exploration of the vital processes in living matter now stands on a firm footing.[1]

Having in the foregoing traced and given the most modern views underlying the principles upon which our modern therapy is founded I have still a few words to say regarding my own views on "nature's antitoxin," which most evidently exists in the protoplasm, and is constantly formed in the living body by the leucocytes for economical and protective purposes. This substance is known to us now as "nuclein."

This cellulized substance, nuclein, takes upon itself the task of performing many complex functions in the physiological economy, and one of the most important, besides that of providing the tissues with its entire nutriment, is to protect its tissues from being invaded by such poisons with which the body is constantly threatened. In fact nuclein is nature's immunizer, and it is also the most important matter in all nature, for it alone is the bearer of life. With slight changes it forms not only the bodies of all plant cells, but also the white and yolk of the egg, flesh and blood, the substance of the brain and nerves, milk and cheese, the skin and hair of animals. While in lifeless nature nearly every kind of stone has a different chemical constitution, in the world of life one and the same fundamental substance forms the basis of the bodies of plants, animals, and men.

We find a very important device that mother nature has provided the cell with a hard shell in case or warfare with bacteria and other poisons which bodies in their momentary lives are endangered with. This soft protoplasm, or "nuclein," as we learned before, would not be able to resist the presence and assault of strange bodies; it is therefore that it is surrounded with a hard shell or envelope, which it prepares as a dwelling and for its protection in a similar manner as the snail forms its shell by secreting over its surface a matter which soon hardens into a firm, transparent enclosure. This shell, known as cell-wall, does not show the most minute opening, but incloses the protoplasm perfectly tight. We might, therefore, liken the cell to an egg, in which the soft living contents are concealed in the hard shell.

But in nature nothing is great and nothing little, and there is room, even in the smallest of nature's cells, for the greatest diversity and development of the powers of life, etc., a continuous formation and transformation, origin and decay, a constant change of matter is going on in every cell; reception and assimilation of food, inspiration and expiration; certain atoms which have become of no use for purposes of life are cast aside, others are taken up from without in their places; as on this food and change of substance depend the renovation of the cell and the maintenance of its life. Evidently not solid substances are appropriated, for we know that the cell is inclosed in a perfectly closed envelope, but liquid and gaseous foods can be easily absorbed. Although the most perfect microscopes have never made any holes visible in the cell-envelope, there is not the slightest doubt that this envelope is porous. Therefore we may understand that, when a cell is placed in a fluid, the envelope absorbs it to fulness, and conveys to the inner protoplasmic body as much as it requires; and, inversely, certain parts of the cell-juices, which the living protoplasmic body does not need for itself, are transpired through the pores of the envelope and become applicable to the use of other cells; and the same may take place with air and gases, etc.

From the many experiments the evidence gathered has shown conclusively that the leucocyte plays the important *rôle* in the physiological life of the beings—as well as in the cell in the vegetable world. That the cell is the manufacturer of an immunizing substance has been again proven by the most recent experiments of Dr. Pheiffer, of Berlin, which substantiates those of mine and others before him. In the last number of *Modern Medicine and Bacteriological Review* there appears an article of exceptional interest, inasmuch as it contains an original article by Professor Metchnikoff, whose theories on phagocytosis are so well known, and goes far to elucidate the idea that the leucocyte is the manufacturer of nature's antitoxin and thereby the normal physiological immunizer.

The interest in this article by Professor Metchnikoff, "The Extra-cellular Destruction of Bacteria in the Organism," lies in the critical comment upon some of the conclusions deduced by Dr. Pheiffer from his experiments on the destruction of cholera vibrios in the peritoneal cavity of guinea-pigs. Dr. Pheiffer observed this destruction of cholera vibrios when the latter were introduced into animals previously vaccinated against this germ, and also in the case of unprotected animals when the vibrios were injected together with a small quantity of serum from vaccinated animals. In both cases Dr. Pheiffer found that they were destroyed outside the cells in the peritoneal fluid, and he believes that this bacteria-killing fluid is secreted by the cellular elements in consequence of a special excitation produced by the injection of cholera vibrios, and that the immunity acquired by guinea-pigs is independent of phagocytosis. Professor Metchnikoff, however, regards this as an episode in the battle between bacteria and phagocytes, and maintains, on evidence supported by experiments, that the leucocytes secrete this bacteria-killing fluid while undergoing the process of degeneration due to the injection of Pheiffer's mixture of vibrios, serum, and broth. That, although unable to engulf the vibrios, they are able still to destroy them by their secretions (nature's antitoxin). Metchnikoff points out that if before introducing the vibrio mixture a few cubic centimetres of broth be injected into the peritoneal cavity, the leucocytes will gather together in great force after a few hours, and if the vibrio mixture be then introduced phagocytosis does take place, and the cholera bacteria are more rapidly destroyed by this process of intra-phagocytosis than by the extra-cellular destruction produced by the condition of Pheiffer's experiments. I must myself agree with some of the views of both these gentlemen. For the last two years this question has interested me so much that I undertook many varied scientific and clinical experiments founded on the foregoing ones just cited. I must say that my clinical experience has also given me proof sufficient to warrant my conclusions. My observations were directed toward diphtherias of different grades, cancers, fevers, and phthisis, with different preparations of the nucleins—among them my own[1]—made from the fish eggs, and that one known as proto-nuclein, also with serums, without culture and in the attenuated form, and the antitoxin diphtheria. Some of my observations with the nucleins in diphtheria, follicular tonsillitis, and pseudo-diphtheria have already been reported and printed in several of the leading American and foreign journals. These clinical truths as reported gave me further stimulus to carry on the more extensive ones, which will follow this present paper. It also gives me great pleasure to see that I foreshadowed that the serums alone, and without the at-

[1] Professor R. Greef's exploration of the motor fibrils of the amœba terricola (Biologisches Centralblatt, November, 1891, pp. 590 and 663) may be mentioned as an illustration of such researches.

[1] The egg nucleins are manufactured for me by special process, and can be supplied by Mr. Oscar G. Kalish, chemist, Twenty-third Street and Fourth Avenue, New York City.

tenuation, have the power of exhibiting their strong bactericidal powers. My own researches are corroborated by those later ones of Pheiffer and Metchnikoff.

In all my work the microscope was not neglected, as I found it a most important witness in my clinical cases regarding the blood counts for its leucocytotic potency.

The efficacy of the antitoxin of diphtheria, and those which have serum as their base, if my conclusions be justifiable, must therefore be dependent upon the nuclein in the serum, and thus its value does not lie in the attenuation of the serum, but in the nuclein that the serum contains, the attenuation being only an extra dynamic irritant by means of which leucocytosis is produced—so giving rise to an increased amount of nuclein, or bacteria-killing fluid, as shown above. This, and this alone, can explain the therapeutic value of antitoxins. From all I have been able to learn from my clinical and experimental studies and from the exhaustive work upon kindred subjects by those gone before, I incline to the belief that both Pheiffer and Metchnikoff have given us the partial solution of this most valuable and interesting problem of immunization and protection against all diseases in that they and myself hold that the immunity is brought about by the bursting of the leucocyte, filled with its ripe or cellulized substance, which in turn is given by the circulatory fluids to the organs whenever and wherever it is needed. The subject is far too recent and yet in its infancy, but it is upon it that our modern therapy must be based.

460 Lexington Avenue.

SOME OF THE CONDITIONS REQUIRING SPECIAL CARE AFTER ABDOMINAL SECTION.

By RUFUS B. HALL, A.M., M.D.,

CINCINNATI, O.

PROFESSOR CLINICAL GYNECOLOGY IN MIAMI MEDICAL COLLEGE; GYNECOLOGIST AT PRESBYTERIAN HOSPITAL; FELLOW OF AMERICAN ASSOCIATION OF OBSTETRICIANS AND GYNECOLOGISTS; MEMBER OF SOUTHERN SURGICAL AND GYNECOLOGICAL SOCIETY, AND OF THE BRITISH GYNECOLOGICAL ASSOCIATION.

The mortality after abdominal section is largely dependent upon the thoroughness with which the patient is prepared for the operation, and the readiness with which complications are met after the operation is completed. In emergency cases, where no time can be taken for preliminary treatment, the after-care of the patient becomes a question of the greatest importance. The after-care of the ordinary case is a source of great anxiety to the operator until the danger period is past, but the emergency case is one that involves greater responsibility and anxiety.

We shall not speak of the after care of emergency cases, but of the after-care of the ordinary case. That the patient may have the best chance for recovery after a section, she should be given the benefit of everything known to science which will contribute in any way to her comfort and welfare.

I shall not consider in detail the preparation of the patient for the operation, but I wish to emphasize one or two important points. It would be quite impossible to establish any fixed rules to be followed in all cases, yet we might say that all cases should have hot baths daily for several days preceding the operation. One of the most annoying conditions to overcome is constipation; it is almost always present. Where time will permit a good routine to observe is this: Five to eight grains of calomel in the evening, followed by sulphate of magnesia in the morning, and every second morning for a week or so, by a saline purge. This, in conjunction with full doses of strychnia given three or four times a day, and proper attention to a diet which does not constipate, will be found efficient. Now that we understand so well the evil effects of the bacillus coli communis, we can better appreciate the necessity of putting the intestinal tract in a good sanitary condition. In addition, the preliminary use of strychnia puts the patient in a better condition to secure an easy and prompt evacuation of the bowels following the operation.

I also attach much importance to a careful examination of the urine. If the kidneys are found defective in the performance of their function, the condition is corrected as far as possible by careful medication, quantities of lithia water, and hot baths. If marked organic disease of the kidney exists, we are made aware of the true condition before the operation and select the anæsthetic that is least likely to be harmful.

The patient always complains of severe pain directly after regaining consciousness, but if she is prepared mentally before the operation for this condition, and told of the great necessity for avoiding morphine, as a rule she can be persuaded to bear the pain. At the end of eight or ten hours, if she has not been given morphine, she rarely complains of pain, but if one dose is given, its use will have to be continued for three or four days at frequent intervals, thus complicating the convalescence. I am seldom compelled to give morphine after an operation; in fact, I have given it to but one patient in two and one-half years. I occasionally give codeia, which does not relieve the pain so thoroughly, but gives some relief. It does not have the bad effect of morphine, and it satisfies the nervous patient's desire that something be done to relieve the pain.

Another condition with which we have to contend is extreme thirst. Almost the first thing a patient asks for is a drink of water, but it must not be given. She must have absolutely nothing in the stomach for twelve to fifteen hours, as it increases the tendency to vomit. Another reason for refusing water is, if we withhold all fluids, the excess of fluid in the peritoneal cavity will be more readily absorbed. After twelve or fifteen hours, if there is no vomiting, give a teaspoonful of hot water, as hot as the patient can stand. It quenches thirst better than cold and has a tendency to prevent vomiting. The thorough physic from the salines, plus the section, creates a great thirst. To allay this and supply the body with water I give an enema of twelve ounces of a saline solution within an hour after the operation, repeating it every four or five hours for twenty-four to thirty-six hours. The patient complains comparatively little of thirst if thus treated.

Ether is more likely to cause vomiting as the patient is returning to consciousness. As vomiting is one of the complications following operations, and once started is difficult to control, everything likely to cause or aggravate it should be avoided as far as possible. It is one of the most annoying conditions with which we have to deal, and, as a general rule, the less you do in the way of medication the first six hours after the operation the better it will be for the patient. Put absolutely nothing into the stomach; give the patient nothing for the vomiting. I frequently have to oppose the views of the family attendant in these cases. He wants to give the standard remedies for vomiting and insists upon it. I have found it to be a fact that the more we put into the stomach the first six hours, the longer the patient will continue to vomit. What she needs, and the best treatment for this condition, is to withhold everything from the stomach.

If, however, the patient continues to vomit for ten or twelve hours or longer, you may look for a cause other than the anæsthetic, probably sepsis, septic peritonitis, or both. Patients as a rule do not vomit longer than six to eight hours after an operation, when the nausea is due to the anæsthetic alone. If, in addition to the vomiting, the patient has a quick pulse, is restless, or the abdomen is distended, the vomiting requires our closest attention, for now it is all important that it be stopped. It is now evident that it is not from the anæsthetic, but is due to a septic condition, and the sooner we can get the bowels moved the better

for our patient. In fact, the vomiting will not be controlled until the bowels are thoroughly evacuated. For this condition I use a fourth to one-half grain dose of calomel rubbed up with a little sugar of milk, placed dry on the tongue every thirty minutes. If the vomiting occurs oftener than every thirty minutes, repeat the dose after each attack of vomiting. This, with a small mustard-plaster over the stomach, with hypodermics of strychnia given every three to four hours, is continued until the bowels are moved. I pursue the same course of treatment for the gaseous distention of the bowels. From six to eight hours after commencing the calomel, I order enemas of two ounces of glycerine with as much warm water, to be repeated in an hour. If this does no good, I use an enema composed of two quarts of warm water, an ounce of turpentine, and two ounces of glycerine, through a rectal tube, passed far up in the colon, instructing the patient to retain it as long as possible. Even if there be no movement, the patient will frequently pass great quantities of gas with the injection and feel much relieved. If the bowels move, the vomiting is at an end at once and convalescence established. Suppose we have done all this and the bowels have not moved? In many of these cases the patient has stopped vomiting by this time, or at least does not vomit so frequently. I then give a seidlitz powder every half-hour or hour, or a solution of citrate of magnesia, two ounces every hour, or sulphate of magnesia, a teaspoonful every hour, and repeat enemas every hour or two. I continue the hypodermics of strychnia in full doses. I persist in this line of treatment until the bowels are thoroughly moved.

There are many dangers following these operations, but those most frequently met with are shock, the influence of the anæsthetic, and hemorrhage. These may be partly guarded against by careful preparation of the patient and thorough work by the operator, yet they cannot be entirely obviated.

As a prevention from shock, two ounces of whiskey with four ounces of warm water should be given per rectum one hour before the anæsthetic and a hypodermic of one-twentieth of a grain of strychnia twenty minutes before. If the patient suffers severely from shock during or following the operation, she should have one fortieth of a grain of strychnia, hypodermically, within three-quarters of an hour after the first dose. If necessary, I would continue the strychnia in one-fortieth grain doses every two hours, until four more doses have been given. This will give the patient's heart strength and reduce her pulse. She should be kept as quiet as possible, surrounded with blankets and jugs of hot water, and the surface of the body not exposed to the atmosphere. I have little confidence in whiskey, given either per rectum or hypodermically, while the patient is suffering from profound shock. Our main reliance must be upon strychnia, digitaline, and nitroglycerine. I frequently combine one or both of these remedies with strychnia. The nitroglycerine is a good remedy for temporary effect, but its effects only last a few minutes, therefore we must rely chiefly upon the strychnia and digitaline.

The bad influence of the anæsthetic upon the heart, kidneys, and the lungs is recognized by everyone. The risk can in some measure be anticipated by proper preparation of the patient. The danger of suppression of the urine is less in sound kidneys than in diseased ones, therefore the necessity of careful examination of the urine, chemically and microscopically, so that we may know something of the condition of the kidneys before the operation. Other things being equal, chloroform is safer in the presence of renal disease and ether in cardiac disease. If there is no contra-indication, I prefer chloroform as the routine anæsthetic. I have found the detrimental effects of ether by diminishing the secretion of urine so universal that I have discarded it altogether in my abdominal work, except in a few rare instances of heart lesion. In such cases where I feel that the danger to the heart from chloroform overbalances the danger to the kidneys from ether, I use the latter.

I wish to emphasize the fact that a man experienced in giving anæsthetics is of great value, and his service greatly increases the patient's chances for recovery. One who will give his undivided attention to the administration of the drug; who is ever watchful of the patient's condition; who is not in any way interested or absorbed mentally in the operation; one who is not ambitious to become an operator himself, and in his desire to witness the details of the operation or some unusual condition encountered, neglects his responsible duty, is to be desired, and in all large cities the services of such a man can be secured. My anæsthetizer, Dr. Colter, uses from a drachm and a half to three drachms of chloroform, keeping the patient under surgical anæsthesia from thirty to forty minutes. It is very rarely that he uses more than three drachms. By thus minimizing the amount of the anæsthetic we lessen the danger to our patient, and that may make all the difference between recovery and death in the ultimate result. Notwithstanding careful preparation of the patient for days preceding the operation, where examination has revealed a lesion of the kidney, and in a few cases where no such lesion could be detected, suppression of the urine has followed the operation. In some of the most obstinate cases the patient has secreted six or eight ounces of urine the first twenty-four to thirty hours, and then there was entire suppression followed by coma.

The following two cases will serve as illustrations of suppression of urine following operations, both in the presence and absence of organic disease of the kidney:

Case I.—Mrs. S——, aged fifty-two, operated upon May 16, 1892, under chloroform for the removal of a very large ovarian cyst. The legs and feet were œdematous when admitted on May 3d. She had secreted but a few ounces of urine in twenty-four hours for several weeks previous. Large quantities of albumin were present and microscopical examination showed granular casts. The day of admission and up to the following morning she suffered so much from dyspnœa that it was thought best to tap her. Several gallons of fluid were drawn, giving temporary relief, and more urine was secreted for the next few days. On the morning of the 16th it was thought best to make the radical operation, notwithstanding one-fifth of the bulk of the urine was albumin. The first eighteen hours after the operation the patient secreted seven or eight ounces of urine and then for a few days from two to six ounces daily. In spite of catharsis by salines, and sweats, the kidneys refused to act. She was so feeble that I feared to use pilocarpine and resorted to corn-pack sweats, which acted nicely and relieved the coma for eight to twelve hours. She again relapsed into her comatose condition and the sweating process was repeated at intervals of ten to eighteen hours. We administered digitaline and strychnia hypodermically, and gave large quantities of lithia water. Her strength was sustained by liberal supplies of liquid nourishment. On the fifth day the function of the kidneys was resumed. The patient made a good recovery and went home at the end of five weeks and is now enjoying good health.

Case II.—A resident of Louisville, twenty-eight years of age, married three years, was visiting friends in this city. Since her marriage she had had a number of attacks of inflammation in the abdomen. The present attack commenced as her previous ones, but more severe. In the fourth week of her present illness I was called to see her in consultation with her physician, Dr. Van Meter, of this city. She was very ill, had a high temperature, rapid pulse, chills, sweats, and vomiting. She had a tumor in the pelvis somewhat larger than a cocoanut. From her clinical history and physical ex

amination I diagnosed suppurating tumor in the pelvis. She was admitted to the hospital on November 5, 1893, and a section was made on the morning of the sixth. A double pyosalpinx and two suppurating ovaries, holding fully a pint of pus, were removed. The anæsthetic was chloroform. She rallied nicely and secreted eight or ten ounces of urine the first twenty-four hours. The next six hours she became drowsy. At the end of twelve hours she was catheterized and less than an ounce of urine removed. Notwithstanding the fact that she had free purgation with salines, profuse sweating from pilocarpine at intervals of eight or twelve hours for the following five days, she was so thoroughly comatose that she was unable to answer questions. For fully twenty-four hours of that time she could not be aroused at all. She was sustained by hypodermic injections of strychnia, digitaline, and nitroglycerine. Pilocarpine had such a weakening effect on her heart that we substituted corn-packs. This acted nicely. On the seventh day she secreted seven ounces of urine and the eighth day twenty ounces, and from that time the kidneys acted nicely without any stimulation. She made a complete recovery and was discharged December 16th, and is now enjoying good health. Only a trace of albumin could be detected in the urine at any time, and never anything abnormal under the microscope. Knowing as we do that suppression of the urine is one of the most fatal complications we have following these operations, the happy termination of these cases is a matter of congratulation and an argument in favor of the treatment adopted.

One of the conditions to be dreaded, especially following inflammatory and suppurating diseases in the pelvis, is hemorrhage. We have been thorough in our operation; liberated all the organs by breaking up the adhesions. We have quite a good deal of hemorrhage during the operation, and the collapse necessarily following the manipulations and loss of blood; we find the patient is not bleeding more than a general oozing when we put her to bed, and so feel perfectly secure. As she rallies we find the hemorrhage starts up. There is bright-red blood welling up through the drainage-tube and soiling the dressing. If the hemorrhage is not too severe, we keep the drainage-tube dry by repeated pumping as often as every ten or fifteen minutes. If the hemorrhage is persistent or increases in quantity, making a profound impression on the patient, reopen the wound and secure the bleeding point. The reopening of the wound is a serious procedure, but under these circumstances there is nothing else left to do, and if this is to be successful it must be done promptly. If we delay until the patient has lost a greater quantity of blood, her life will be sacrificed. It is now a question of saving the patient from a death by hemorrhage, just as if you had a hemorrhage from the stump of an amputated limb; not so quick, but quick enough. I have little doubt that many patients have been lost from this cause. With the patient in the Trendelenburg position, it is not a difficult matter to find the bleeding point and secure it. It may be that the ligature has slipped or cut through the pedicle, or possibly a bleeding point has been overlooked during the operation; but no difference what the source of the hemorrhage, it must be controlled or the patient will surely die. There is nothing in this work that tries my courage as a hemorrhage under these circumstances. The following cases very fairly illustrate accidents of this kind:

Mrs. M——, of Troy, operated upon in the Woman's Hospital, April 1, 1891, for the relief of a chronic inflammation in the pelvis. Adhesions were extensive and firm. Both appendages were removed. The patient suffered from nausea following the operation. There was the usual amount of drainage from the drainage-tube during the day. The patient was very unruly, not heeding the instructions of the nurse; she persisted in straining desperately at each act of vomiting, and at 11.30 that night while retching felt something give way in the abdomen and called the nurse's attention to it. On inspecting the dressings, they were found saturated with blood and blood running from the drainage-tube. I was notified by telephone and at once repaired to the hospital. I reached the patient within an hour after the accident and found her semi-conscious, and a pulse that was scarcely perceptible. With the assistance of two nurses, without removing the patient from the bed, I at once cut the stitches in the abdominal wound and found that the ovarian artery was cut through by the ligature and the pedicle more than half cut off. This was seized and ligated without difficulty, the abdomen was irrigated and closed, and the patient had no further trouble from this source. She made a prompt recovery. I have no hesitation in saying the patient would have died within a very short time without surgical interference.

We occasionally see large varicose veins in the pedicle in operation, both for the removal of ovarian cyst and fibroid tumor: these are a source of post operative hemorrhage that has not been duly recognized by the profession. I reported a case of this kind operated upon in October, 1892, where the vein ruptured on the proximal side of the ligature the second day following the operation. On January 21, 1895, I removed a large fibroid tumor from Miss W——, Mt. Vernon, at my private hospital. It was observed there were very large varicose veins on one side. This condition was commented upon during the operation. Everything went well, the incision was closed. While applying the dressings we noticed blood running from the drainage-tube. I immediately cut the stitches, reopened the abdomen and found a pint or more of blood in the pelvis and a rent in the vein on the distal side. The vein was ligated separately. The patient made a good recovery. If the drainage-tube had not been placed in this patient, we would have had no means of knowing of the hemorrhage until too late to save her life. The shock from the loss of blood would have been misconstrued as the shock of the operation. Enough has been said to emphasize the statement made before, that these are trying cases which do not admit of any half-way measures.

MASTURBATION IN THE ADULT.

By EDGAR J. SPRATLING, M.D.,

MATTEAWAN STATE HOSPITAL, FISHKILL-ON-THE-HUDSON, N. Y.

MASTURBATION being in itself a habit fraught with dangers to its devotee just in proportion as the nervous stamina of the individual is lacking, one would naturally think with horror of its octopus-like grasp within the walls of every institution intended for the care and treatment of those unable mentally or morally to stand on an equality with his free fellow-man. And well may those in whose care the insane are placed regard it as an arch enemy, for hand in hand with its boon companion, sodomy, it stalks through every ward, entangling its victims more hopelessly with each passing night.

In women the road to its cure is an endless and monotonous journey, for nothing short of ovariotomy will be found to deserve even the term palliative; clitoridectomy, anatomically and physiologically, could be but a failure, blistering only cruelty.

Among men the case is not so hopeless, for there anatomy is partly in the operator's favor. Of the treatments we might speak of blistering the glans penis, but only to condemn it as an uncalled-for cruelty; the possible beneficial effect is so transient, while the untoward effect is often so lasting upon the patient mentally in the way of a feeling of resentment, that it is doubtful if one could ever justify such a proceeding.

The various kinds of apparatus that are intended to

prevent the mobility of the foreskin, are one and all to be let alone as unsatisfactory and unsuccessful, if not actually mischievous, by concentrating the patient's attention to that locality. Preventing the opportunity for the practice is simply out of the question. Castration is not to be considered for many and very obvious reasons.

Complete section of the dorsal nerves of the penis (as I have previously advocated) is a rational procedure, but rather too radical for constant routine practice. The cases require the greatest care in the selection for this operation, and even then with all due care one will generally have to encounter the most strenuous objections and later the bitterest reproach and condemnation from the patients and from their relatives—though the object sought may have been obtained.

In all cases, taken as they come, circumcision is undoubtedly the physician's closest friend and ally, offering as it does a certain means of alleviation and pronounced benefit, granting as it does immunity from after-reproach. Those cases in which the glans presents a moist, semi-oily appearance, with papillæ strikingly developed about the corona, long thickened foreskin, pliant and giving, large and often tortuous dorsal veins, go to make up a picture that is exceedingly tempting to the surgeon's scissors. The whole operation, when the scissors and continuous suture are used, takes only from four to six minutes—and time is a great consideration, especially in the case of the insane, even though local anæsthetics may be used. To obtain the best results one must cut away enough skin and mucous membrane to rather put it on the stretch when erections come later. There must be no play in the skin after the wound has thoroughly healed, but it must fit tightly over the penis, for should there be any play the patient will be found to readily resume his practice, not begrudging the time and extra energy required to produce the orgasm. It is true, however, that the longer it takes to have an orgasm, the less frequently it will be attempted, consequently the greater the benefit gained. Tubes, rings, clamps, and directors, devised as aids in circumcision, are worse than useless on account of the time involved in their manipulation, and also because they necessitate the use of a knife instead of scissors, thus inducing more hemorrhage, and most likely necessitating interrupted sutures instead of the continuous. We may not be sure that we have done away with the possibility of masturbation, but we may feel confident that we have limited it to within the danger lines, which is the primary object sought, as we are from the outset striving for the hygienic, not the moral, benefit—the latter is usually too far from our reach to even consider.

The younger the patient operated upon the more pronounced the benefit, though occasionally we find patients who were circumcised before puberty that require a resection of the skin, as it has grown loose and pliant after that epoch. Mental depression following circumcision is practically unknown, and the only patients in whom there is any but the most pronounced physical gain, are those above fifty years old. And we might note, too, that after that age masturbation seems to have very little influence on the health, the patient seemingly having passed the period at which the drain can do much harm. Many of the boys and younger men begin to show marked gain in weight and even in mental activity within ten days after the operation. Generally the patients do not object to the operation when its nature and object are fully explained to them; indeed, some of the most intelligent insist on it being done, acknowledging their inability to free themselves of their habit voluntarily.

Bequest to the New York Post Graduate Medical School and Hospital.—The New York Post-Graduate Medical School and Hospital has received a gift of $5,000 from the estate of the late Henry M. Cram.

THE VALUE OF PHENYLHYDRAZIN-HYDROCHLORATE IN THE DIAGNOSIS OF DIABETES MELLITUS.

By FRANCIS A. WINTER, M.D.,

FORT HANCOCK, TEX.

ASSISTANT SURGEON, UNITED STATES ARMY.

The employment of phenylhydrazin as a test for the detection of grape sugar has been a subject of comment and observation since its first employment by Fischer, of Erlangen; and the subsequent endorsements by Von Jaksch and Utzmann in Europe, and of Bond in this country, have contributed a measure of prominence to the salt second to that of no other agent. Some observers have been most laudatory in their opinions of its worth, and would make it an agency of supreme value. My interest in the general subject of urinalysis, and the recollection of a signal disappointment with the salt, has prompted an investigation of the matter, and while the inquiry has brought forth no results of significant novelty, it has yet shown me at once the value and the demerits of the test in the final adjudication of the grave and momentous question as to whether a given urine is, or is not, the index of diabetes mellitus.

It has been my endeavor, in a research extending over some months, to consider the agent from the stand-points of—1, delicacy; 2, the influence of substances and "constituents" in the urine (adventitious and constant); 3, uniformity of response, with certain presence of glucose; and 4, its comparative value as a test. I have made the observations with both water and urine for solvents, and have taken at different times such drugs, etc., as would probably modify my own urinary excretion. In some instances I have employed the urine of physically sound soldiers living in barracks.

The method followed in the work has been, in the main, as follows: A space of three centimetres of a test-tube is filled with the salt; an equal quantity of sodic acetate having been added, the tube is filled half full of the suspected solution and then shaken to dissolve. The liquid is slowly raised to the boiling-point and kept there for thirty seconds, when the tube is immersed in cold water and the sediment examined in one hour, and again in twenty-four hours. The result, in presence of glucose, should be masses of brilliant, canary-yellow, acicular crystals, taking the general form of sheaves, an arrangement similar to the crystals of tyrosine, rarely found in urine.

This technique I have varied in many ways, hoping that departures from a standard procedure might influence the result. The boiling has been prolonged for various periods, from thirty seconds to half an hour (in the extended ebullition the solution is kept at original strength by immediate condensation and return to the flask); solutions have been cooled gradually, and the sediments examined at different times, from a few minutes to a week, after the experiment. It may safely be considered that these variations are of no material influence. I advert to this because of the varieties of technique advocated by different authors.

A carefully prepared ten per cent. solution of glucose in urine is taken and diluted as one requires, through decimal gradations, to one-tenth per cent., and so on. Each dilution is treated as shown above, and the results carefully noted. With solutions of from ten per cent. to one and one-half per cent. strength, the reaction is characteristic and constant. There is a brilliant yellow precipitate, showing the microscopic characters noted above. These crystals are most abundant in the stronger solutions and decrease in number and show alterations of definitive character, *pari passu*, with the attenuation of the solution, until at one per cent. strength they become comparatively rare, with a patent change in morphology, showing in many instances as

small globular bodies, central to a number of delicate, sharp radii, or spicules, resembling somewhat the crystal of ammonum urate ("hedgehog"). The preservation of a crystalline character is unequivocal, though much patience is often demanded in finding them. Below one-half per cent., the reaction is practically negative. Numerous bodies appear, wanting in shape and color the qualities of phenylglucosazone (the product). The prevailing type is a round, dark-brown body, showing no crystalline structure, and refracting light much as does a fat cell. There are also to be found small polygonal plates, slightly brown at the periphery. Both the foregoing structures are in no sense characteristic or recognizable as phenylglucosazone.

The reduction is little, if at all, influenced by other material in the urine. Excess of urea and uric acid provoke no change; the urine of a carbohydrate diet (urea 23 to 27 gm. in twenty four hours) reacts abundantly; the ingestion of benzoic acid and subsequent elimination of hippuric acid, in excess, is responsive when glucose is present (the urine of herbivora is a suitable vehicle); the salicylates, camphor, turpentine, asparagin, and the various synthetic antipyretics, have no influence; a urine rendered light green by use of phenol, and reacting with the tri-nitro phenic coloration to nitric acid is suitable. All of the above agents provoke no response unless glucose be added. Subsequent to this admixture the reaction is unimpeded. With large doses of chloral the urine gave a precipitate of small reddish-brown globular bodies, similar to those noted above, as coming from very weak glucose solutions. Glucose added to this urine results in the characteristic crystals, accompanying the globular bodies.

As to the uniformity of the test's response (sugar in quantity being present) my experimental work is affirmative. From the notes of a case occurring in civil practice some years since, I think its unfailing indication of sugar to be assailable as a general proposition. The urine in question was given me by Dr. Bryson, of St. Louis, and had long been considered sugared. Just at this time I was working with phenylhydrazin and had been much gratified by the truly splendid results of its employment. I applied the test to the urine in question, and was surprised to find it unresponsive. All the usual reduction tests had been responsive, and under fermentation the urine lost in specific gravity the approximate equivalent of six per cent. sugar. During some months I made frequent attempts to obtain phenylglucosazone, but always unsuccessfully. The fermentation was sedulously used for control. I thought the presence of sugar unequivocally shown, and regret that the polariscope was not employed to emphasize the fact. Other urines examined with the same salt were responsive, as were aqueous solutions of glucose.

After a protracted experience with the test I have concluded that while it has great merits it is certainly amenable to criticism. For delicacy the copper (Fehling's) test has proven, in my experience, its superior. Fermentation is equally delicate and significant. Solutions of one-half per cent. strength may be estimated, even quantitatively by yeast, while the faintest response with phenylhydrazin is difficult of establishment.

In the instance of failure noted above the classical uncertainty of the ordinary reduction tests was met by fermentation, and Marshall's glycosuric acid was excluded by the same agency.

In my opinion the singularity of the result must be attributed to one of those occult and mysterious products of excretion which, by its presence, in some unfathomable manner, inhibits the reduction. In the light of contemporaneous discoveries and identifications this view seems not untenable, and while my own sedulous efforts have failed to show any source of modification, I can easily imagine the ultimate definition of the matter in the hands of the trained physiologist.

Failure in this instance has certainly furnished me with a timely caution, and emphasized the conviction that, aside from fermentation and the polariscope, we possess no single test absolutely final to a decision of the glycosuric character of urines.

My experience leads me to think that phenylhydrazin may have a great measure of value in inquiries of this kind, but I cannot esteem it a *summum bonum*, and should, personally, prefer fermentation.

Its greatest source of value seems to me to lie in its constancy to glucose only, for if phenylglucosazone appear, one may safely consider glucose present. Quantitatively I have found the test of no value. I have endeavored to establish a satisfactory scale from the number of crystals appearing in the field, but they are inconstant and ununiform. A word of caution respecting the salt used is *à propos*. Merck's preparation is reliable, while others I have found unsatisfactory.

DIAGNOSIS AND CHRONOLOGY OF ABORTIONS.[1]

By EDWARD A. AYERS, M.D.,

PROFESSOR OF OBSTETRICS NEW YORK POLYCLINIC; PHYSICIAN IN CHIEF MOTHER'S AND BABIES' HOSPITAL, ETC.

THE weak spot in the relations of our profession to the management of abortions is our want of accurate knowledge of the anatomy and physiology of the uterus, decidua, and fœtal membranes, and particularly of the chronology of the membranes in the first three months of pregnancy. Embryology is a very incomplete science as yet, and a most difficult, though fascinating, department of biology. A famous writer said of his essay, "I have not had time to write a short one." Our authors and investigators have not had time to simplify embryology. Virtuosity is impossible in the pioneer. Space has not been given to the various parts of the subject of embryology in proportion to their relative clinical needs. Thus the fœtus has been splendidly described. And it is truly a beautiful picture to observe through the microscope's widening eye the solid field of uniformed cells line and deploy until the forming outlines of liver, lung, or spleen appear. To witness the formation of a calibre out of a lamination of cells is a profoundly impressive suggestor that "there is a divinity doth shape our ends," and that thrills the scientific heart. But the development of the fœtus has little part in our proper understanding of cases where life or health are at stake from an interrupted pregnancy. Its length, weight, and limb formation largely comprise the important points.

In the study of the fœtal membranes and decidua, our text-books develop the subject by following separately a single tissue, as the amnion or allantois, from their origin to their formation, leaving the mind much confused when we endeavor to comprehend their advancement as a whole.

For the handling of patients in abortion we need to know how the tissues are arranged at four weeks, six weeks, eight weeks, ten weeks, and three months. If we have this knowledge, the uterus becomes as glass, and the questions of treatment are answered almost as soon as asked. The complexities of embryology, taken at any one period, are sufficiently difficult of comprehension, when we consider that the anatomical arrangement of the embryo and its membranes changes greatly from week to week, that what is to-day largely decidua and slightly ovum, is in a few days mostly ovum and little decidua; or this fortnight is mostly chorion and in the next placenta; we do not wonder that the subject has been too often relegated to the back shelf of the library.

Our society discussions generally begin and end with consideration of the causes and treatment of abortions. Shall we complete the threatened abortion, shall we dilate the cervix or use a tampon, shall we empty the

[1] A paper read before the Brooklyn Medical Society.

uterus, and if so, with a curette, or placental forceps, or the finger? Shall we use gauze or irrigation in the uterus, or both? These are important questions, but they have received a vast amount of attention compared to those involving a fine ability in diagnosis.

Will you pardon my endeavor to state some of the salient points that aim to strengthen the department of diagnosis.

The diagnostic tissues of pregnancy are: Fœtus, amnion, chorion, and decidua. As the latter has been claimed by well-known German writers not to be pathognomonic of pregnancy, it is necessary to explain my position. In 1889 I published a very carefully prepared paper on "The Decidua in the Diagnosis of Extra-uterine Pregnancy." In that paper I claimed that if decidual cells were found in the uterus, a pregnancy either within or without, that is an extra-uterine, existed, or had recently existed. Olshausen, Ruge, and others have declared against this, claiming to have found these embryonic cells in membranous dysmenorrhœa. My special point in that paper was that if we obtained by exfoliation or curettement decidual cells from the uterine cavity, and no fœtus and membranes were present in the cavity, then an extra-uterine pregnancy existed.

Without going into the discussion here, let me say that, whether I shall ultimately be proven right or wrong, I fully believe that though exceptions to the rule that decidual cells are pathognomonic of pregnancy may exist, this much may be taken, without hesitation, as a safe rule: That endometrium, which is conspicuously made up of decidual cells, and particularly where such membrane is soft and free from fibrous tissue, is the decidua of pregnancy only. The recognition of any of these four diagnostic tissues is always desirable, but not always easy, owing to the broken form in which we may receive them, and the many alterations that may take place in their structure.

The Fœtus.—There is no difficulty in recognizing the embryo, if it is present. It may be absorbed previous to the expulsion of the ovum.

The Amnion.—There is no tissue liable to be mistaken for the amnion. It is very thin, transparent, and microscopically found to be free from blood-vessels. Its surface is smooth and glistening.

The Chorion.—Normal chorion has a white, sheepskin-like base, from which radiate straw-colored villi branching into two to five single offshoots. These villi are to be differentiated from fibrous shreds only, and are therefore easily recognized. They have, instead of thread like free ends, club-like tips, which are thick enough to be recognized with the naked eye. In medico-legal testimony one would be justified in declaring the presence of pregnancy if only a single villus were obtained from the uterus. The villus consists of a single layer of flat epithelium, enclosing an afferent and efferent capillary, surrounded with a very light connective tissue. The one abnormal change of importance in the chorion is that of cystic degeneration. The metamorphosis is absolute, and the well-known grape-like mass is the result. Once seen or once felt, this pathological tissue can never be mistaken. It is a group of watery cysts of sizes ranging from a pin-head to a large grape, attached by a pedicle to an opaque membrane; and may only fill an ounce vial or a wooden pail.

The Decidua.—This is much the most difficult pregnancy tissue to recognize, because of its less distinct and individual construction, and especially its great variety of pathological appearances. Normal decidua, when exfoliated in the first week of pregnancy, has the general form of the cavity of the uterus. It presents on its outer surface somewhat the rough surface of leather, having loose fibres from having been torn from its base, the musculo-glandular layer of the uterus. Its inner surface is smooth, and like the outer surface of the skin. It is thrown into folds. Of course the arrangement of the three decidua will depend upon the period of pregnancy. The three conspicuous forms the decidua present are: The intra-uterine decidua of an extra-uterine pregnancy, in which we find a thinner membrane than in normal intra-uterine pregnancy, of uniform thickness throughout, very flexible, and having no reflexa inside. Next the form present in normal gestation, in which we find it as described above. On cutting open such a decidua we find the reflexa usually lying pendent from the upper or fundal part, not filling the cavity of the vera, thinner than the latter, and smooth on its outer part. This decidua is very vascular, and therefore red to the shade of muscle, but not of the same texture to the eye. It is about two millimetres thick in the first month, the vera and reflexa getting thinner in the second and third months. The third variety of decidua is such as we see in its most exaggerated form in the uterine mole. Do not understand me to say that a mole is decidua, as the amnion is a part of that tumor. But the mole shows the highest degree of thickening of the decidua, and is really a form of general hyperplasia. A large part of its structure is intermingled blood-clot.

Chronology.—I wish now to briefly consider the most practical phase of the subject, namely, the arrangement of the membranes at certain periods of pregnancy. The advantage of an accurate knowledge of the growth of the ovum as a whole lies in the fact that where we can name the week of pregnancy, having, for instance, secured the embryo in a partial abortion, we can decide far more scientifically what treatment the uterus requires than by simply resorting to a curette. I will consider the behavior of these tissues in abortions at the same time.

At Four Weeks.—The decidua is much the most important membrane at four weeks' gestation. The reflexa is fully formed, but does not occupy more than three-fifths of the uterine cavity. Consequently on introducing the finger within the internal os it would, after having passed the vera at that point, come in contact with a body like a polyp at a distance of a little over one-eighth of an inch. The ovum is about the size of a large hazel-nut. The chorion is fully formed on all sides, with the exception of the normal bald spot, the size of a well dilated pupil. The amnion, on opening the chorion, will be found to embrace the embryo, but not to have expanded to more than half the distance to the chorionic periphery. The embryo will be found lying free within the amnion, and about the size of a small Lima bean. The little elevations that are to form the extremities appear upon the embryo. The latter is a little larger than a good-sized pea. The characteristics of an abortion at this time are: A hemorrhage that is apt to be classed as a severe menstruation, an effort of nature to catch up after having missed one period, the probable escape of the ovum in blood-clots unnoticed, and a temporary cessation of hemorrhage, with its recurrence in a few days, and more uterine pains, accompanied with the expulsion of the decidua. Or, instead of decidual expulsion there is a gradual disintegration of the decidua that may leave the uterus finally clean, involuted, and well, or the development of a slow endometritis, with heavy feeling, excessive menstruations, etc.

While it is best to interfere with the curette and get the uterus clean when much hemorrhage or excessive menstruation result, in the former case acting at once, and in the latter after a menstruation, yet so many women fully recover unaided, and interference carries risks, it is best to use sharp discrimination in the individual cases, letting most of them alone.

At Six Weeks.—The decidua is still prominent and important. The vera is unchanged, the serotina has grown and thickened, the reflexa is undergoing an atrophy that began in the fifth week. The latter is nearer to the internal os. The chorion has expanded to the

size of a silver half-dollar, and enjoys a luxuriant growth of villi. The amnion is nearer the periphery, but is still separated from it. The embryo has doubled in size, and its extremities show an appreciable length. The characteristics of an abortion at this period I will consider with those at eight weeks.

At Eight Weeks.—This is a very frequent period for the occurrence of abortions. It is the menstrual period that would have been, and it is the period of marked transition from chorionic nutrition to placental. This latter metamorphosis requires that the villi on three-fourths of the chorionic surface shall atrophy, with a corresponding growth at the placental site. In tissues of their delicate construction the readjustment of cell-pressures is readily provocative of capillary ruptures and so leading to abortion. At eight weeks the chorion and remnant of the decidua reflexa fully occupy the cavity of the uterus. The amnion also occupies the entire cavity of the chorion. The fœtus measures 3.5 ctm. and has the hands and feet well outlined. The decidua, having grown thinner, is less apt to come away complete, particularly as the chorion is more apt to rupture, and by the collapse resulting make it doubly difficult for the uterus to separate and expel the membranes. If the chorion escapes from the uterus without rupture, it generally escapes alone, leaving the decidua behind. This decidua should be removed at once, and the best medium for its removal is the finger. A sensitive patient will require an anæsthetic. The finger inserted within the cervix, the fundus must be pressed down until the finger can reach the fundus and thoroughly separate all the membrane before withdrawing the finger. Where the cervix is tight (it is seldom hard if there is still tissue within that should come out) the curette may be substituted for the finger. When the chorion ruptures during uterine dilatation, an unfortunate accident, it may be necessary to dilate the cervix, as it now becomes hard for the uterus to force open the former.

At Ten Weeks.—The fœtus and partially formed placenta are now the prominent parts in the uterus. The temporary villi of the chorion have largely disappeared, also the reflexa, leaving a thin layer composed of the amnion and chorion to be felt, should the finger be introduced within the cervix. The prominent characteristics of abortion at this time are expulsion of the fœtus and umbilical cord alone; their expression with the amnion, which may or may not be unruptured; the cord having separated from the forming placenta at its junction with the latter. The placental tissue is apt to remain in the uterus for a varying time and cause hemorrhage, and to become foul-smelling. It should be removed soon after the expulsion of the fœtus. We rarely obtain a specimen at this period of a complete exfoliation of decidua, and all the other membranes and fœtus, on account of the ease with which the sac ruptures.

At Three Months.—The placental form is now well established, and the uterine contents behave much as they do at full term, with these differences, that the placenta is less firmly put together, and is more firmly united to the uterus. There is danger, therefore, of masses of placenta being retained, even though much may be expelled.

I have time, now, for only a brief summary of the variations in the treatment of abortions that are demanded at different weeks of pregnancy. As a general proposition it is fair to say that whenever an abortion takes place, none of the tissues that are present only in pregnancy should be left in the uterus. The uterus certainly objects to fœtus, amnion, and chorion, once the ovum dies, and it cannot use the decidua either in repair or in forming new endometrium. It must get out before a healthy state can be inaugurated. It cannot be said that we should always interfere and remove these tissues, for though nature may be inefficient, there is room for much bungling on our part. Our individual judgments in given cases must decide.

At four weeks' abortion we should, as a rule, keep down hemorrhage and wait on nature. If called upon to interfere, it will be the decidua that we will needs remove. The curette, and not the finger, should be used.

At six and eight weeks the chorion will cause the most trouble. Either finger or curette may be indicated in cleansing the uterus. A strip of iodoform gauze should be introduced to the fundus to prevent secondary hemorrhage, render a foul cavity pure, to stimulate repair, and favor drainage.

At ten and twelve weeks the fœtus comes out first, and the other tissues are apt to need artificial removal. The finger is to be preferred to any instrument. Gauze should be used at these times. Small, repeated doses of ergot are desirable for twenty-four hours.

In cystic degeneration of the chorion the cervix should be dilated with a Barnes's bag, and the contents scraped out with the finger or hand. Gauze should be introduced immediately, and left twenty-four hours. Ergot is needed. In uterine mole the uterus should be let alone, barring the need of checking hemorrhage. A mole is a very solid body and comes away whole, leaving the cavity clean. Having devoted this paper to the diagnostics of abortions, I must express regret at touching upon the extensive subject of treatment in the most superficial manner.

CHANCRE OF THE TONSIL, WITH REPORT OF A CASE.[1]

By HENRY B. HITZ, M.D.,

MILWAUKEE, WIS.

Of the various forms of syphilitic infection that daily demand the attention of the physician, among the rarest is found chancre of the tonsil. Of 77 cases of chancre in the buccal cavity collected by Fournier, but 1 was upon the tonsil.

Diday collected 671 cases of erratic chancre, but did not find any back of the anterior pillars. This writer reported 8 cases in the year 1861–62. In 1891 Szadek reported 4, and Grauducheau 1. Since this time several cases have been reported in the journals, but I have not been able to get track of them. Morell MacKenzie saw but 7 cases in his long and varied experience.

The most graphic and satisfactory account of chancre of the tonsil is given by Donaldson, in the *Medical News* of August 15, 1885, the substance of which is to be found in the "Reference Handbook of the Medical Sciences," and a *résumé* of which I give as follows:

This disease is less uncommon than is generally supposed, although difficult of recognition, owing to the absence of history, and the atypical appearance of the lesion. It occurs most frequently in women for obvious reasons, although it has been innocently acquired by kissing, instruments, etc. Out of the 7 cases seen by MacKenzie, 6 were females. Owing to the exposed condition and the character of the tonsillar structure, the explanation of its appearance in this locality is plain, the large tonsillar crypts affording ample opportunity for the lodgement and ready absorption of the virus.

The signs of infection usually begin with slight redness and swelling, without perceptible induration, followed later by pain during deglutition, and increased redness; and still later by hypertrophy and superficial erosion, having an indurated base, while more or less glandular enlargement occurs upon the affected side. The rapid hypertrophy and general tumefaction is in

[1] Read before the meeting of the Wisconsin State Medical Society, West Superior, June, 1895.

itself an important and constant sign. Second only to this is the superficial erosion, increasing to an actively ulcerating surface, usually covered with a thick grayish-white pellicle of somewhat granular character.

The glandular enlargement upon the affected side is constant and of an indolent type, but never goes on to suppuration. The difficulty of diagnosis is usually due to the absence of history, either through the reticence or ignorance of the patient, and to its unusual situation and diversity of appearance. It must be differentiated from malignant disease, especially epithelioma, tuberculosis, secondary and tertiary syphilis, diphtheria, and gangrenous ulceration of the tonsil.

Morell MacKenzie suggests that if an ulcer remains obstinately on the tonsil, in spite of treatment for four or five weeks, a suspicion of its syphilitic nature may be indulged in.

Donaldson suggests that if a lesion upon the tonsil has been of slow unilateral development, with pain and glandular enlargement upon the affected side, without febrile reaction, and is superficial, with a grayish-white pellicle; if the patient has a history or even the suspicion of syphilitic exposure, and has not been subject to simple tonsillitis; if the sore has appeared from fifteen days to three weeks after exposure; and if the whole is followed in due time by a secondary outbreak, we are certainly justified in diagnosing chancre of the tonsil.

Generally unilateral, the duration of chancre of the tonsil has been thought to be shorter than the same lesion elsewhere. In Donaldson's case the secondary eruption appeared within a week after patient's first visit, and before the sore had healed.

Having given a cursory glance at the history of this disease, I shall now ask you to review with me the following case, which came to my notice November 21, 1894:

M. R——, male, aged twenty-eight; weight, 180 pounds; family and personal history good, except for rheumatic diatheses. About eight years ago patient was treated for chancroid, and subsequently for gonorrhœa. Of late he has been dissipated, often becoming intoxicated, and while in this condition visiting houses of prostitution. About five weeks prior to the above date and several weeks after last having interviewed a prostitute, he noticed on arising one morning a slight soreness of the throat, which became progressively worse. Upon the fourth day, the pain being severe, he consulted his physician, who diagnosed "tonsillitis," and treated him accordingly for the subsequent four weeks. At the end of this period, having but slightly improved, he consulted Dr. N. Dodge, who after a casual glance at his throat referred him to me.

Careful examination revealed the following pathological condition: Upon the left tonsil was a large ovoid ulcer, about the size of a dime, the surface of which was covered with a grayish-white necrotic coat. A deep sulcus divided this surface into two vertical parts, while a small quantity of sero-purulent discharge exuded therefrom. Its base was firm and indurated, and its lower border could only be seen by forcibly depressing the tongue; when this was done it appeared elevated above the surrounding and hypertrophied tonsil, the whole mass of which approached the median line. Owing to the swelling, the pillars were forced asunder, were thickened and of an angry, dark red color, having upon their upper margins several superficial ulcers, evidently from contact with the large ulcer during deglutition. Externally there was swelling and tenderness under the corresponding angle of jaw, and notwithstanding the excess of adipose in this case, the submaxillary and left cervical glands were felt to be distinctly enlarged. Careful examination elsewhere failed to show any glandular enlargement, either in the post- or right-cervical, supra trochlear or inguinal regions. Thorough inspection of the genitalia developed nothing but an old stellate cicatrix upon corona. The skin upon the chest appeared "blotchy," but attracted attention only in so far as its being the possible premonitor of a secondary eruption.

Having a suspicion of the probable nature of the case, careful inquiry into the patient's habits was made, but failed to elicit any other information than that of several sexual contacts with various prostitutes within the preceding three months.

Upon this visit the patient was given a placebo, and told to return in two days, at which time he appeared with a light, though unmistakable macular eruption upon his chest and abdomen, which he observed with surprise when his attention was called to it. Again the genitalia were carefully examined, with the same result as before, except that two bright maculæ were seen upon the dorsum of the penis. He complained of having had considerable muscular pain since his previous visit, with general malaise and restlessness. Pain during deglutition was less pronounced, and there was slight though marked improvement in the appearance of the throat.

There being no longer doubt as to the diagnosis, mercury was administered in the form of the green iodide in rapidly increasing doses, with inunctions at night, and patient was informed of his condition.

On the 26th he again appeared, with this time a well-marked maculo-papular eruption upon his chest, abdomen, and limbs, while upon the face and neck it was just beginning to appear. The improvement of the local lesion had rapidly progressed, although the induration still persisted. On the 28th abdominal pains, diarrhœa, and other symptoms of the systemic action of the mercury appeared, but were quelled under the administration of a lead and opium pill, and did not again appear while under my treatment.

On December 3d, at the persuasion of a friend, the patient visited Dr. A. H. Levings, who told him he had syphilis, but said nothing about the seat of the original lesion. On this day he appeared with a mild acute laryngitis. The local lesion had now entirely healed, but there was little diminution of the induration. The eruption upon the body had almost disappeared, and could be but faintly seen on the face, while upon the forearms and hands it was still pronounced.

On December 6th he was referred back to Dr. N. Dodge for systemic treatment. At this time he was receiving one and a half grain of mercury in pill-form daily, with nightly inunctions.

During the temporary absence of Dr. Dodge, on April 6, 1895, the patient again appeared at my office with large ulcers in both nasal cavities, mucous patches in the buccal cavity, a marked superficial glossitis, alopecia, and a rupia upon the scrotum.

The interest in this case centres in the primary sore, and in the subsequent rapid appearance of the secondary symptoms. Dismissing with a word its syphilitic nature, of which there is absolutely no doubt, the question arises: Was the tonsil the real seat of primary infection?

In the absence of all signs of recent venereal disease, either extra- or intra-urethral, or of any hypertrophy of the inguinal glands, the known presence of a large indolent, indurated ulcer upon the tonsil, resisting local treatment and antedating by at least five weeks (and probably longer, as pain is not the earliest symptom) the secondary outbreak; the history of prior exposure; the chain of enlarged and tender lymph-glands upon the affected side, and their absence in other regions, and the well recognized rapid appearance of the secondary phenomena when the primary lesion is located here, have led me to diagnose, without hesitation, this case as one of chancre of the tonsil, a diagnosis also unhesitatingly concurred in by Dr. J. Steele Barnes, who saw the patient with me upon his second visit.

Progress of Medical Science.

Diagnostic Ureterotomy. — Within the last year Dr. Kelly has performed three operations, at the completion of which he feared the ureter had been ligated, as it appeared in each instance to be enlarged (*Annals of Surgery*). It was impossible to ascertain certainly whether this accident had occurred without either taking out a large number of ligatures which had been placed in the ureteral area or catheterizing the ureters. In either event the danger would have been much greater to the patient than the operation about to be described. To remove all of the ligatures in the ureteral area and relegate all of the bleeding vessels would have consumed too much time, and the catheterization of the ureters would have been still more impracticable. For these reasons, he determined to resort to ureterotomy as the easiest solution of his dilemma. Accordingly he located the ureter at the pelvic brim, snipped the peritoneum over its course, and made a longitudinal incision, one-half centimetre in length, into the lumen, through which he passed a small ureteral sound down into the bladder. In two cases of the three he found the ureters free, the enlargement being simply due to the pressure of the pelvic mass previous to the operation. In the third case, however, he found that the ureter had been included *en masse* with a large area of bleeding tissue in the pelvic floor. He at once removed the constricting ligature, and was able to pass the sound into the bladder. By this simple operation much valuable time was saved, and uninterrupted recoveries in each case justified the statement that the operation is without danger. In closing the slit in the ureter, he used delicate mattress sutures in two cases. The third required four sutures on account of the persistent oozing of urine. These sutures were very lightly passed into the outer coat of the ureter, not entering its lumen. The cases in which he resorted to this operation were myoma uteri, carcinoma uteri, and dense pelvic inflammatory disease. All of the patients made complete recoveries, and there have been no apparent ill effects from the operation up to date. He used gauze drainage in each case, and there was not the slightest urinary odor detected at any time on the dressings. For cases in which there is grave doubt as to whether the ureter has been ligated or cut, he earnestly advises this diagnostic measure.

Chemical and Pathological Characteristics of Milk.— Dr. Rotch states that the infants' digestive functions have been from time immemorial adapted to the digestion of an alkaline or neutral fluid, not to an acid one. Human milk is the food on which the greatest number of infants live and thrive, and on which the smallest number die proportionately to any other known food. Whether the moderately alkaline reaction of this milk is an important factor in the problem of infant feeding, is a question not yet decided. We should at least be very suspicious of an acid breast milk. The best results obtained in artificial feeding are those in which the food is alkaline in reaction. This is usually accomplished by the addition of an alkali. Mr. G. E. Gordon, in the course of extensive observations of milk, found that cows fed in certain parts of Kentucky upon blue grass, and also in other parts of the West, produced a milk which was alkaline, and which remained so for a number of hours after milking. Analysis of this food showed its composition of nitrogeneous and carbo-hydrate elements to be in the proportion of one to five and one third. It is known that cows fed on comparatively dry foods produce comparatively acid milk. Extensive experiments prove that cows fed freely on sugar beets, which supply a large amount of carbo-hydrates, produced a faintly alkaline milk. These experiments were conducted with the utmost care, with a large herd for three months, with the following uniform results: The cows fed partially on beets showed neutral or faintly alkaline reaction; the cows that received no beets showed a uniformly acid reaction. This milk was carried twelve miles. The milk from one-third of the herd which had been fed on beets was added to that of the other two-thirds. The reaction was even then found to be faintly alkaline. This is of great interest as showing that the product of the cow cannot only be made to correspond in reaction to that of human beings by means of perfectly natural feeding, and under perfectly normal conditions, but that this alkaline modification can be produced to such a degree that one-third of the milk is sufficient to destroy by its alkalinity the acidity of the remaining two-thirds.

A further series of experiments was undertaken to determine the source of the bacteria which are found in milk. It was found that the direct milking of the first half, performed by sterile hands, with strict antiseptic precautions, showed a milk with a comparatively large number of micrococci and fine bacilli. It was found, further, that the milk drawn through a sterile cannula was practically sterile, and that the milk drawn in the second half of the milking by hand was uniformly sterile. These experiments provided us at once with a means of producing a milk practically sterile, but not sterilized. This experiment also seems to prove that the bacteria which are found in cows' milk do not necessarily come from external sources, whether they be of the cow herself or of her surroundings, but that they may also come from some part of the milk tract between the udder and the end of the teat.—*Archives of Pediatrics.*

Total Extirpation of the Patella.—According to Dr. Kummer, total extirpation of the patella can be performed without impairing the patient's gait or markedly interfering with movements of the knee-joint: The operation is indicated in cases of tubercular osteitis of the patella, provided the articulation remains yet intact. Extirpation can actually prevent the development of articular lesions and thus save the knee-joint, provided the operation is resorted to sufficiently early. In cases of tubercular osteitis of the knee-cap, total removal of the bone offers better chances in regard to recovery than scraping out the morbid foci. Dr. Kummer adduces an illustrative case—a girl, aged twenty-five, with primary tuberculosis of the right patella, but with a perfectly intact knee-joint—in which he made excision of the bone, with excellent results. When shown to the Société Médicale de Genève, about two months after the operation, the patient was able to extend her right lower limb as under normal conditions; would kneel with perfect freedom, and without any pain or discomfort: could walk four or five hours daily without lameness or fatigue, or run up and down staircases with ease, etc. In short, the only inconvenience caused by the absence of the knee-cap consisted in a relatively weakened extension of the corresponding limb. A similarly successful case of total removal of the patella is reported by Professor Kaufmann, in *Correspondenz-Blatt fur Schweizer Aerzte.* The patient, a married lady aged thirty-three, was suffering from fungoid osteitis of the left knee-cap, of eight years' standing. A month after the operation she, being frightened by a fire next door, tore off all dressings and ran out of her house, having swiftly descended a staircase. Since then her knee-joint has been perfectly movable and her gait normal. Dr. Kummer mentions further two cases of primary tubercular osteitis of the patella in boys, in which the whole of the bone was removed by Professor Th. Kocher of Berne. An interesting case of total excision of the patella for acute necrosis has also been published in *The Lancet* by Mr. Page, of Newcastle-on-Tyne. The patient recovered with a perfectly useful limb.—*Provincial Medical Journal.*

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

New York, September 28, 1895.

IS CANCER INOCULABLE?

THE recent report of the death of a physician of this city as the result of supposed inoculation of cancer, while in attendance upon a case of that disease, has again revived, in the public press, an interest in the general question of alleged communicability of that form of malignant growth. The gentlemen who were interviewed on the probabilities of such a condition of things are not only wisely non-committal, but judiciously hide their identity behind the general statements of "eminent specialists."

The subject is, however, by no means a novel one. From the time that the malignancy of cancer was recognized the question of communicability has borne the brunt of the most earnest investigation, and the hope of its solution has stimulated the most ingenious experimentation of earnest investigators. The results of all such studies have been entirely negative. There are no proofs of which we have any knowledge that cancer has ever been directly or indirectly propagated from one human being to another. It is true that there is published an occasional case in which there would appear on superficial examination to be a direct relation between cause and effect, but when such are critically examined the theory of propagation vanishes in face of a conscientiously critical analysis. At best they are coincidental circumstances following the general law of accidents. Experiments in the lower animals have thus far amounted to nothing, and practically we are as much in the dark regarding the true etiology of cancer and its real methods of dissemination as ever.

The investigations in these directions have been exceedingly interesting, although mostly instructive from a negative view. Among these are the experiments of Dr. D'Arcy Power, made in 1894 and published in September of that year in the *British Medical Journal*. The animals experimented upon were very old or very young white rats, which may be assumed to be more vulnerable than adult animals which run wild. These animals were kept in low wire cages resting on soil taken from those districts in England in which cancer most prevails. This soil was thoroughly mixed with fresh cancer tissue, and kept moist with water in which cancer tissue had been ground and pulped. The rats were from time to time sprayed with a thin cancer pulp, and their mucous membranes were kept in a state of chronic irritation so that the protozoon, if any existed, might find a suitable medium for its reception and a favorable soil for its growth. The rats, six in all, lived in this way for about eleven months. Two died, one from cold, the other from intestinal perforation by a tape-worm, and four were killed. A careful examination was made in each case, but in none could a trace of cancer be found anywhere either by the naked eye or under the microscope.

These facts, although reported at the time in the MEDICAL RECORD, are interesting enough in the present connection to deserve repetition.

Again we remind our readers of a report in this journal two years ago of experiments made by Dr. Gratia, of Brussels. The results of his investigations justified the following conclusions: 1. The parasitic nature of cancer has not been satisfactorily proved. 2. The direct or indirect contagiousness of this neoplasm has not been demonstrated even in individuals of the same species. 3. In those instances in which the clinical history of a patient appears to prove inoculability, it has been shown that an exceptionally strong predisposition to cancer already existed, awaiting only the slightest and most ordinary irritation for its full development. In other words, the supposed inoculation amounted to nothing beyond a possibly determining traumatism. The latter, it seems to us, is the key-note of the whole question. A person predisposed to any disease is always an easy victim when any definite exciting cause presents itself, while one without such tendencies escapes every time. The melancholy case in point was undoubtedly one of predisposition to malignant disease, that developed in due time, the supposed inoculation from a cancerous patient having no more causative relation to it than any other purely coincidental circumstance.

THE REGISTRATION OF MIDWIVES.

IN spite of the very strenuous efforts of the medical profession of Great Britain to enforce the education of midwives and insure their proper qualification by registration, it would appear from a recent discussion in the London *Times* that the object is very far from attainment. This will be somewhat of a surprise in view of the fact that England has been supposed to be a long way in advance in her practical solution of the problem. Now, however, it is boldly stated that a large number of infant lives are yearly sacrificed, especially in the Whitechapel and other poor districts, by the incompetence of the ordinary charwoman, who regularly officiates as nurse to the lying-in woman. All this proves how futile are the present laws governing registration after years spent in the most laudable efforts in that direction. The main difficulty appears to be in the want of education of the ignorant classes to the necessity of aseptic precautions in guarding against the numerous and fatal sources of puerperal infection. The Englishman of the lower class is more than jealous of his rights, and among these of being independ-

ently dirty is not the least. His traditional right of guarding his hovel as his castle, in which the king cannot enter without an invitation, explains his stubbornness in combatting every innovation that may jar the rhythm of his jealously guarded personal privileges. In many respects the poor of this and other cities in America are on the same level, especially those in tenement-house districts. In our own endeavors, however, to insure proper qualifications for midwives, we are not to be discouraged, as with the exceptional powers of our health authorities it is quite possible to so enforce necessary regulations as may compel our lower classes to obedience, rather than to invite the opposition of argument or the disputation concerning their supposed individual rights. The fundamental principle of all sanitary laws rests upon the safety of the majority; the control of the birth-rate and the reduction of infant mortality are the chiefest of these in estimating the stability and prosperity of the State. As there is no excuse in these days for negligence in these matters, there is no argument, even in the face of the most stubborn opposition, for creating and enforcing the requisite regulations to such ends.

THE EXAMINATION FOR POLICE SURGEONSHIP.

The civil service examination in this city for one vacancy in the surgeoncy of the police called together sixty-eight candidates for the position. This circumstance shows not only the active competition for such places, in which a salary of three thousand dollars is assured, but also proves that the profession takes it for granted that there has come at last a time when fair play in such appointments is virtually guaranteed by the new Board of Police Commissioners. The applicants were much above the average grade that appear on such occasions, and, on the whole, represented a high standard of professional attainment. We can predict that a very large proportion will pass satisfactorily. The questions asked were reasonably just, and were calculated to call forth a practical knowledge equal to the usual emergencies of the office. The average age was thirty-three years, and comprised for the most part men who are engaged in actual practice, with a large percentage of hospital graduates. While there is only one vacancy, caused by resignation, in a corps of fifteen, there will probably be altogether three additional places to be filled, in case the requisite amount of appropriation for such purpose is made.

Taking this into account in connection with the fact that one or more of the present force is beyond the age limit, there may be, by future forced resignation, a corresponding chance for six or more places to be filled. There is no doubting the fact that the time has come for the infusion of new blood in the board and the vacation of some of the places that have been so long held by political appointees. No one can doubt that from the sixty-eight applications there will be obtained much more than a sufficient number of first-class men to fill all present and future vacancies. The profession will now watch with interest the result, in the hope that the best may win.

THE MIRACLES AT LOURDES.

The English journals contain a number of accounts of the wonderful cures that are being daily performed at Lourdes. Mr. Chauncey M. Depew, on reaching America after a European trip, also gave to reporters an interesting account of an alleged miraculous cure, of which he was personally cognizant. Lourdes is altogether having a decided "boom."

The description of the way in which the pilgrims to this place are treated shows to what an extraordinary state of nervous excitement and expectation patients who come there are subjected. Hardly anything is lacking to produce, in a most intensified way, both psychical and physical shock. The patients are brought into the grotto during the chanting of hymns and amid the noise and excitement of the multitudes about them. Just as the nerves have reached the highest possible tension, the patient is suddenly plunged into the icy cold bath; he is then withdrawn, and believes he is cured. Naturally, some extraordinary effects are produced. There can be no doubt, however, that these effects are all due to this unique combination of exciting and stimulating experiences. Nor do we question at all but that a careful investigation of the subsequent history of the numerous cases of alleged cure would show that there was a relapse in all the serious organic cases, and probably a relapse in many of the functional ones. We are informed that a young physician, well known for his careful scientific methods and for his accomplishments as a neurologist, is investigating, in a most painstaking way, various cases that are going to Lourdes, and is following up these cases after they have been through their treatment. A report upon the effects of the alleged miraculous healing from such a source would undoubtedly have a practical value as well as be of scientific interest.

SOME THERAPEUTIC TRADITIONS.

Dr. Walter G. Smith, President of the Royal College of Physicians of Dublin, gave an address recently upon the subject of therapeutical traditions. It is always instructive to hear the judgments of practitioners of long experience upon therapeutics, and Dr. Smith's contribution on this subject contains much that is suggestive and useful. The learned orator, in giving his address, did not attempt to cover the ground of therapeutics in any systematic way. He begins by talking upon the subject of diet in its relation to diseases of the skin. He avers that many years ago he reached the conclusion that the effect of diet in the treatment of this class of cases was very slight. Some text-books upon diseases of the skin give minute dietetic details, details which he believes to be of really little value, and which would not be followed by the authors of the book if they had such diseases themselves. With the exception of such diseases as urticaria, certain

of the erythemata, and some cases of eczema, there is little reason to particularize in the matter of diet. The patient should be told to follow the simple rule of moderation in eating as well as drinking; total abstinence from alcohol is often a thing very much needed. One of the most generally believed traditions in dietetics of skin diseases, according to Dr. Smith, is the prohibition of salt food, most patients, he says, being assured that they cannot be allowed to touch a morsel of ham or bacon. Dr. Smith does not believe in this special tradition, and thinks that salt food has no special disadvantage, except that salt meats are not, as a rule, as digestible as those which are fresh.

Dr. Smith next alludes to the common belief regarding the efficacy of lithia and other alkaline water in the treatment of gout and allied affections. This is a subject to which we have ourselves often referred, and it is not necessary to go over Dr. Smith's line of argument now. He shows that the few grains of lithia or other alkaline salts present in the mineral waters cannot have any particular effect in modifying the conditions which underlie gout or lithæmia. He says that he never prescribes lithia-water to such patients, but there is no objection to their taking it if they choose. A pint of lithia-water is, to all intents, equivalent to a pint of pure water. The elaborate analyses, he adds, of the various springs, all arising, perhaps, from the same geological stratum, only prove that many persons are unable to see a joke, and cannot perceive the difference between "tweedledum" and "tweedledee."

Another therapeutic superstition which Dr. Smith attacks, with perhaps less force and justice, is the use of pills coated with keratin, or other substance which is insoluble in an alkaline medium. Dr. Smith would have us believe that the intestinal contents is not alkaline as a rule, but acid, and that, consequently, the theory on which these pills are given is false. We believe that keratin-coated pills have rather fallen out of use, while the general fact upon which they are based is true. The contents of the intestines is at times, and in certain parts, acid, to be sure, on account of fermentative changes, but the general reaction of alkaline and therapeutic measures that are based on this view may be assumed to be correct.

Heroic Treatment of Pneumonia.—There are still some people who believe in blood-letting as a remedial measure. In the *Gazette des Hôpitaux* for August 27, 1895, Dr. De Duplaa de Garat has an article on the "Specific Treatment of Pneumonia," in which he counsels bleeding from the arm upon the first appearance. The following day a second venesection is to be practised, if the fever continue, and, if there is no improvement, still another on the third day. Occasionally, says the writer, the disease is jugulated by the first bleeding, more often by the second, and usually by the third. If the latter do not suffice, however, we must bleed again on the fourth day. The patient is further depleted by an absolute fast, no food at all being allowed until the third day of convalescence. Instead of burying all his pneumonia patients, the writer claims that he cures them all without exception.

News of the Week.

Misery in Italy.—In a letter to the London *Truth* "Ouida," the novelist, writes: "Official statistics state that in Italy there are 100,000 persons dying of pellagra, 6,000,000 living on malarious land, 1,700 communes in which corn is rare, 1,400 communes with scanty and foul water supplies, 600 communes which have no doctor within reach, and over 300 communes which have no burial-place." As "Ouida," when not writing romances, is given to exaggeration, and as the journal in which her letter appeared seldom lives up to its name unless by accident, we may hope that Italy is not in quite so bad a way.

China has twelve hospitals throughout the Empire, and but twenty-five educated medical men for the population of 400,000,000.

The Morals of the British Practitioner are carefully and tenderly regulated by a number of estimable gentlemen who compose what is known as the General Medical Council. This august board of censors meets several times a year, and tries the cases of those who have tried to let their light shine before men, whether through a paid ad. or a friendly press notice. But when a lawmaker breaks the law, when a vigilant censor himself permits his name to be mentioned in the columns of a lay journal, things have indeed gone wrong. It is then the duty of the medical press to administer the rebuke that the councillor cannot be expected to administer to himself, and this is the way the *Lancet* does it: "We notice in the columns of a lay contemporary an announcement that 'Sir Dyce Duckworth, the well-known physician, has gone to America. He intends to be back in this country about September 16th.' We are too often compelled to reprove practitioners with advertising, or to call attention to their being advertised by injudicious or stupid friends, and we cannot ignore similar occurrences in the case of leaders of the profession, although we feel sure that the objectionable notice has been inserted without Sir Dyce Duckworth's knowledge or leave. The curse of publicity which necessarily attends upon those in any prominent position makes it, perhaps, more difficult for them than for humbler members to avoid this sort of thing, but owing to their position it is of all the more importance that they should take every means to prevent such notices getting into the public press." We are truly sorry for anyone writhing under the curse of publicity, but the only remedy that we can suggest to our suffering colleague is that he come to this country again and remain here, for we have so many in prominent positions that he might with less difficulty preserve his incognito.

Dr. Nelson Isham, who was the oldest living graduate of Yale Medical College, died at Little Falls, N. Y., on September 18th. He was born in Bolton, Conn., in 1805, was a member of the class of 1828, and was surgeon of the Ninety-seventh Regiment, New York Volunteers.

The Cholera in Russia.—In the province of Volhynia, Russia, during the week ending August 24th

5,849 cases of cholera were reported, and 2,134 deaths therefrom. In the province of Podolin, for the ten days ending August 31st, 101 cases of cholera and 45 deaths were reported.

Responsibility for Remarks at the County Medical Society.—The meeting of the New York County Medical Society on Monday last was one of especial interest and excitement. The trouble arose from an appeal by Dr. Frank Van Fleet to the society against the decision of the Comitia Minora. The Comitia had decided that the society could not assume responsibility for remarks made by Dr. Van Fleet at one of the meetings of the society which resulted in the institution of a suit for $40,000 damages against Dr. Van Fleet. The remarks in question by Dr. Van Fleet were made in criticism of an advertisement of an optician published in the Directory of the County Medical Society for 1894. A very warm discussion ensued, in which the sympathies of the society were apparently strongly in favor of Dr. Van Fleet. However, the following resolutions were finally adopted :

Whereas, It has come to the notice of this society that one of its members has had suit brought against him for remarks made before this society ; and

Whereas, The Comitia Minora has decided that the society has no responsibility in the matter ; and

Whereas, The member mentioned has appealed to the society from the decision of the Comitia Minora, and the members of this society desire to know just what their rights and privileges are in matters of this kind ; therefore be it

Resolved, That a committee of five, composed of the President of the society, Drs. Richard H. Derby, Joseph D. Bryant, D. B. St. John Roosa, and Henry D. Noyes, be appointed to consider just what the merits of the case may be, and to determine what action, if any, the society should take.

Vaccination and Marriage.—In Sweden and Norway a person cannot be legally married until after the production of a certificate attesting that the affianced parties bear genuine vaccine marks.

Dr. Adolphe von Bardeleben, the well-known surgeon and professor at the University of Berlin, died in that city on September 24th. He was born in Frankfort-on-Main, on March 1, 1819.

Diphtheria in St. Louis.—Health Commissioner Starkloff of St. Louis has made a report to the Board of Health to the effect that diphtheria is practically epidemic in that city, 170 cases having been reported since September 1st.

Professor Pasteur was reported by cable the other day to be dying. This report has since been denied, but it is stated that his health is very feeble.

The Summer School of Medicine, of Chicago, has been incorporated under the name of the Illinois Medical College. It held its first commencement on September 4th.

The Physicians' Alliance Monthly.—*The Physicians' Alliance Monthly* is the title of a journal devoted to the financial interests of the members of the Alliance. It contains among other things thirteen and a half pages and fifty-two columns of names of persons resident in New York, whom, we presume, belong to the class who do not pay their bills. We did not suppose that the world was so bad

The First Railway Hospital in the United States was started in 1868, at Sacramento, Cal., by the Central Pacific Railroad. The first surgeon was Dr. S. B. Thorn, of Sacramento. The first hospital of the Missouri Pacific Railroad was established in 1879 by Dr. J. W. Jackson. Dr. A. W. Ridenour, of Massillon, O., was the projector of the National Association of Railway Surgeons. Dr. Frederick H. Caldwell was the first to practically equip and run a hospital car on his system of roads.—*Tri-State Medical Journal.*

A Medical Mission College has been organized in Chicago. It is to have, says the *Chicago Medical Recorder*, a dual faculty, one section of which is composed of clergymen and the other of members of the faculty of various homœopathic colleges.

Medical Education of Women.—The University of Durham has thrown open its portals to women, having obtained a supplementary charter, enabling it to grant to women any degrees except degrees in divinity. According to Polk's "Medical Register," in 1893 more than three thousand women were engaged in the practice of medicine in the United States, and a later census puts the number at a little more than five thousand. There are from thirty-five to forty co-educational medical colleges, besides a good many independent colleges which only receive women. *The Practitioner* discusses the question whether any of these five thousand women have reached distinction in the medical world, and the editor says that he confesses that he is not acquainted, by reputation, with any one of the number. This, he modestly admits, may only be due to the limitation of his own knowledge, and we are inclined to allow the admission. There can scarcely be any intelligent physician to whom the achievements of Dr. Putnam-Jacobi, for example, and perhaps half a dozen others, are not known.

Obituary.

JOHN LAW CAMPBELL, M.D.,

NEW YORK.

JOHN LAW CAMPBELL, M.D., seventy-two years old, member of the County Medical Society and the Academy of Medicine, and for more than twenty-five years physician to the New York Orphan Asylum, died on September 22d at his residence in this city. He had not been well for several years, but his death was unexpected and was due to angina pectoris. Dr. Campbell was born at Daanesburg, N. Y., and was a graduate of Jefferson College, Philadelphia, and of the New York College of Physicians and Surgeons. He was a trustee of the Franklin Savings Bank, and for forty years a practising physician in New York City.

He was an elder in the West Presbyterian Church and was always prominent in religious and charitable work.

Society Reports.

MISSISSIPPI VALLEY MEDICAL ASSOCIATION.

Twenty-first Annual Meeting, held in Detroit, Mich., September 3, 4, 5, and 6, 1895.

THE Association convened in the Strassburg Academy, and was called to order by DR. H. O. WALKER, of Detroit, Chairman of the Committee of Arrangements. Prayer was offered by the REV. MARCUS A. BROWNSON, of Detroit. DR. WALKER then introduced MAYOR PINGREE, who paid an eloquent tribute to the medical profession, and extended a cordial greeting to the Association. The Address of Welcome on behalf of Detroit physicians was made by DR. J. HENRY CARSTENS, of Detroit.

President's Address.—DR. WALKER presented the President of the Association, DR. WILLIAM N. WISHARD, of Indianapolis, who delivered the Presidential Address. He said the importance and advancement of Detroit was represented by the standing and intelligence of the local physicians. He referred to the beginning of the four years' course in medical colleges, and said the fear that the new rule would operate to the disadvantage of the smaller schools was unfounded. The President urged the advisability of publishing the records, papers, and discussions in some manner to make them accessible to all members. He recommended a permanent Executive Committee, and regretted that the large number of papers necessitated the holding of two meetings at the same time. He commended the preparations for the Convention, and pledged his earnest efforts to the promotion of the profit and pleasure of the Convention.

The reports of the Secretary and Treasurer were read and accepted.

The Gold Combinations as Alteratives.—DR. THOMAS HUNT STUCKY, of Louisville, read a paper with this title. At a meeting of the Medico-Chirurgical Society of Louisville, April 5, 1894, the author had the pleasure of exhibiting a series of cases who had been taking the preparations of gold and arsenic, known to the profession as *arsenauro* and *mercauro*. He was under the impression at that time that the good effect claimed was produced in three ways: 1, By stimulation of the secreting glands of the stomach; 2, by the probable alterative effect upon these secretions; and 3, that probably there was a local antiseptic influence exerted. The class of patients in which he had used the preparations were people afflicted mostly with consumption, Bright's disease in its various stages, chronic hepatic troubles, and convalescents. He made it a rule with all these cases to withdraw all medicine except the combinations of gold and arsenic. He had selected from a series of cases four or five, which he detailed.

CASE I.—Patient, a male, sixty years of age, with tuberculosis. History good. Eight drops of the mercuric bromide of gold and arsenic were given hypodermically every four hours, this treatment being continued for two months. No deleterious results were noticed. On the contrary, he is decidedly better; physical condition, color, appetite, and bodily strength improved.

He reported a few cases out of a large number to demonstrate in his judgment, conclusively, that by the combinations of gold and arsenic we have an agent acting as neither of the minerals do when administered separately; or, in other words, we have an entirely new agent in so far as therapeutical action is concerned.

The author then dwelt at considerable length upon the chemical differences between the chloride of gold and sodium and the bromide of gold and arsenic (arsenauro) with reference to their therapeutical action and subsequent elimination. He believes that in the action of the combination of bromide of gold and arsenic, it is entirely different from any therapeutic agent known. As compared with mercauro, iodine, or the combinations of iodides, the action of gold in the combinations named is greater and intensified; that these combinations enter into the circulation as gold and arsenic and spend their force and exert their influence in an alterative way upon the glandular system; that a marked alterative effect is exerted upon all sclerosis (non-malignant); that it is not only a blood-maker, but a blood builder; that it not only increases the quantity, but the quality of the corpuscles; that under its use hæmoglobin is markedly increased; that it is eliminated by the kidneys; that they produce no irritation either when given per orem or hypodermically.

Cases corroborating the beneficial and curative effects of the preparations mentioned by the essayist were reported by Drs. A. P. Buchman, I. N. Love, and William F. Barclay.

Legitimate Pharmacy.—This paper was read by DR. WILLIAM F. BARCLAY, of Pittsburgh. He defined legitimate pharmacy as that which meets the necessities and demands of the regular medical profession and the people. The medical profession is entirely separate and distinct from pharmacy. Medicines are divided into four classes—patented, proprietary, non-proprietary, and secret. There are a large number of cures, mixtures, and tonics bearing the name of their originators and deserving of consideration as proprietary preparations. Pharmacists and physicians are interdependent and should work together. Legitimate pharmacy has called into service educated and able men, but the incompetent and dishonest have got in too and cannot be too severely condemned. Pharmacists make errors, but physicians are careless, too, in writing prescriptions. Physicians should not favor any particular pharmacist and should not receive pay from them. On the other hand, it is unworthy and unprofessional for pharmacists to prescribe drugs or medicines. Legitimate pharmacy should protect the people from the nostrum makers. Physicians have a right to require the highest skill and competence upon the part of the pharmacist, both for his own interests and the good of his patients.

Cod-Liver Oil.—DR. F. E. STEWART, of Detroit, considered the powerful stimulant action of cod-liver oil on nutrition, also demonstrating with specimens the difference in the color of oil digested from fresh livers, and that prepared from putrid livers, the former being pale, golden, or light brown, according to the number of hours digested, and the latter dark brown. The darker oils contained more extractive matter. Dr. Stewart said the text-books contained many errors regarding the preparation of cod-liver oil.

DR. I. N. LOVE, in the discussion, conceded the merits of the paper, but expressed himself as rather sceptical as to the value of cod-liver oil. He declared that there was danger of our getting too professional, and said that that which brings relief to the patient is to be commended. He favored proprietary remedies which have come to the profession through pharmaceutical channels.

Uterine Fibroids—When to Operate.—DR. TOD D. GILLIAM, of Columbus, O., read the paper. The medical and electrical treatment of uterine fibroids is to-day in a very unsettled state. While it cannot be denied that amelioration or even recovery has followed such lines of treatment, there has not been that degree of uniformity in results calculated to inspire confidence. To the author's mind there is no better field for a competent observer than the study of the natural history of uterine fibroids. It will enable us to determine the true value of so-called curative agencies. It will insure a more certain prognosis. It will give the proper cue to surgical interference. If out of one hundred

cases, ninety suffering women can be restored to lives of usefulness and happiness, would it not be better to give them a chance? No surgeon is justified in doing hysterectomy or the more serious operations for uterine fibroids when the patient has not experienced sufficient trouble to make it a menace to her life.

Tubercular Peritonitis.—This paper was read by Dr. L. H. Dunning, of Indianapolis, Ind. In the domain of surgery there is no more attractive study than tubercular peritonitis. The mode of invasion, forms of the disease, diagnosis and treatment were considered in the paper, and finally a brief history of five cases was given.

Tubercular peritonitis with effusion is now universally considered a surgical disease. Even in the acute suppurative cases abdominal section yields a sufficient number of successes to render its employment imperative. Senn excludes all forms of the disease from surgical treatment except the exudative form. Manclaire gives as the chief contra-indications to surgical treatment the generalization of the lesion and the existence of profound systemic infection. Linder analyzes the results in two hundred and five operations with a mortality of 7.5 per cent. The deaths resulting in most of these cases were from collapse. In cases of involvement of the tubes and ovaries, they should be extirpated. His experience in two cases leads him to the belief that we should, if possible, avoid using silk ligatures in tying the pedicle when it is necessary to remove the uterine appendages.

Case I.—Mrs. A. B——, aged fifty-six. Consulted the author concerning the extirpation of a fibroid tumor of the uterus. She had passed the menopause five years previously, but the tumor had gradually increased in size. At the time of examination it had reached the umbilicus. There was a small amount of fluid in the abdomen, and on opening it probably a quart of clear, straw-colored fluid ran out. The peritoneum and intestines were studded with innumerable small grayish deposits of the size of a millet seed. Similar deposits thickly studded the serous covering of the tumor. The intestines were agglutinated, but were not adherent to the tumor. After removal of the tumor by supravaginal hysterectomy and ventro-fixation of the stump the abdominal cavity was irrigated, and then leaving the drainage-tube just behind the stump, the abdominal incision was closed. Recovery.

Case II.—A diagnosis of ovarian tumor had been made, and examination revealed an accumulation of fluid in the abdomen, which was encysted. The uterus fixed, and an immovable mass was outlined in the pelvis upon the right side, which the author believed to be a small ovarian tumor surrounded by inflammatory exudates. An exploratory incision was made, and three gallons of dark fluid evacuated from the abdominal cavity. A small tumor was felt in the pelvic cavity. The incision was enlarged, the tumor enucleated, and the pedicle tied off together with the Fallopian tube. The left tube and ovary were likewise extirpated. On exposing the abdominal and pelvic cavities to view, it was seen that the viscera were thickly studded with small grayish deposits. Microscopical examination demonstrated the presence of tubercle bacilli. Patient now, eleven months after operation, in good health. Two of the five cases reported by the author terminated fatally.

Dr. Gilliam, of Ohio, believes that where we have tuberculosis of the ovaries and tubes, it is better to remove the uterus too.

Dr. J. Frank, of Chicago, asked whether any of the members who had operated for tuberculosis of the peritoneum had noticed a recurrence, or how long the patient was immuned from further attack.

Dr. Humiston, of Cleveland, O., reported two cases upon which he had operated successfully.

Dr. R. S. Sutton, of Pittsburgh, had seen a good many cases of tubercular peritonitis, upon several of which he had operated successfully. Until within a year he had been in the habit of washing out the cavity with hot water, but now he pays no attention to it, but simply opens the abdomen and cleans out everything. He is convinced that while hot water does no harm it does no good, in that it has no influence upon the disease. He believes in removing, as far as possible, all diseased organs.

Dr. Henry O. Marcy, of Boston, operated in 1887 for the first time on a case of tubercular peritonitis, the patient making an easy recovery. He had operated several times since then for this disease with excellent results.

Dr. A. H. Cordier, of Kansas City, Mo., called attention to the tact that Mr. Wells, as early as 1862, operated for tubercular peritonitis, simply incising the abdomen and draining, thus curing his cases. He thinks that drainage is the principal thing that brings about a cure in this disease, but how, is not definitely settled. He said the theory had been advanced by Dr. Morris, of New York, that it is due to the admission of saprophytes into the peritoneal cavity.

Dr. Bayard Holmes, of Chicago, related an interesting case of adhesive peritonitis cured by operation.

The paper was further discussed by Drs. W. S. Caldwell, of Freeport, Ill, Entriken, of Findlay, O., and B. M. Ricketts, of Cincinnati, O.

Dr. Dunning, in closing, said that Linder's observations were the most complete of any, and he found very little tendency to recurrence of the disease where it was primary and of the adhesive form; but where the disease was secondary and of the adhesive form, there was a strong tendency to recurrence. His own experience had not been sufficiently extensive to furnish reliable data in this regard.

Hysterectomy for Puerperal Sepsis—When shall it be Performed?—With a Report of Four Cases.—The author of this contribution was Dr. Bayard Holmes, of Chicago. The paper was divided into four parts. 1. A report of four cases of puerperal sepsis treated by four different methods. 2. The pathology of puerperal sepsis in various stages. 3. Curettement in the hands of its advocates. 4. Puerperal sepsis as a cause of death in Chicago, New York, Brooklyn, and in the Charity Hospital at Berlin, with an abstract of 79 deaths from puerperal sepsis in 6,635 cases.

Case I.—A multipara, twenty-six years of age, of Irish extraction, having a history of tuberculosis of the lungs, confined under unfavorable circumstances, with retained placenta, post-partum hemorrhage, delivery without an anæsthetic with the hand of the physician, arrest of hemorrhage, gradual sepsis, failure of curettement, and death seven weeks after confinement.

Case II.—A woman, thirty years of age, normal confinement, with sepsis appearing upon the fourth day, of a mild character, gradually increasing until six weeks after delivery. Temperature was high, pulse rapid, and symptoms of peritonitis with obstruction of the bowels. Laparotomy. Removal of the right broad ligament, tube, and ovary; drainage through the vagina; death after eight days, without peritonitis, from phlebitis and pulmonary embolism.

Case III.—A multipara with gonorrhœal history, an abortion followed by pelvic inflammation, peritonitis and obstruction three weeks after delivery. Removal of both tubes and abdominal drainage; death after ten days, without peritonitis, through phlebitis and pulmonary embolism.

Case IV.—A multipara, thirty-two years of age, delivered by a midwife, with a bad history of puerperal infection, rapid onset of a mild infection, no curettement. Obstruction of the bowels, vomiting six weeks after delivery with evidences of peritoneal effusion. Laparotomy; removal of the uterus and its adnexa, abdominal drainage, and recovery. This uterus and these appendages were carefully examined microscopically. There was evidence of necrotic endometritis, suppura-

tive endometritis, suppurative metritis, suppurative lymphangitis in both tubes with abscess of the ovarian ligament upon the right side and adjacent peritonitis. The blood-vessels throughout the broad ligaments were found indicating a progressive infective thrombosis. The uterine tissue was filled with pus cells, occupying the perivascular and lymph spaces with occasional obliteration of large blood-vessels. A great number of mastzellen were found throughout the infected tissues. The author held that the progress of puerperal infection was in this case through infective thrombosis and suppurative lymphangitis, and that the removal of both tubes and drainage would have been ineffectual. He then proceeded to recount the pathological findings in cases of non-infected puerperal women dying from accidental causes during the first, third, and sixth weeks after labor, and also cases dying at somewhat similar times after labor, stating the comparison of the normal and abnormal uterine and peri-uterine tissues.

In the city of Chicago during the years 1881 to 1894, inclusive, there were 2,127 deaths from puerperal fever. In New York during six years ending May 31, 1880, there were 250,000 deaths, of which number one-sixth were females, and 2,236 of these deaths were due to the puerperal state. Of these 1,250 were due to puerperal infection. In Brooklyn, with 112,000 deaths during the same period, 53,000 were females, and of these 867 died of the puerperal state, 462 dying of puerperal sepsis. These figures show the importance of the subject.

The question of treating puerperal infection by evidement or curetting was discussed by presenting the work of its own advocates, showing that out of 7,600 cases of labor in the hands of one of the advocates of curettement, 101 were treated by repeated curettement and irrigation. Of these 96 recovered and 5 died.

An abstract of the history of these five cases was presented, showing that there was every reason to believe that after curettement had failed hysterectomy would have proved efficient in saving the patients.

A series of 6,635 cases of confinement occurring in the Charity Hospital, in Berlin, under the care of Hensoldt, Schwarze, Huenermann, and Hochselter during four successive years, were then analyzed. Seventy-nine deaths from all cases occurred. Of these deaths, 33 resulted from puerperal sepsis, and in order to fully understand the possibility of these cases, a short epitome of the history of each was presented, showing that only 3 out of 633 cases were of such a character as to give rise to the suspicion that they might not have been saved by hysterectomy.

The author gave the following conclusions: 1. Puerperal sepsis has its origin in the endometrium and usually travels by the lymph-channels or by the thrombosed blood-vessels and the lymph-channels together. 2. It still causes almost one-half of the deaths which occur in the puerperal state. 3. Curetting is ineffectual in many cases of puerperal sepsis. 4. The removal of an infected broad ligament and the drainage of a pelvic abscess or peritonitis is often ineffectual. 5. Hysterectomy should be performed, therefore, in such cases of puerperal infection as do not yield to uterine curetting and irrigation. 6. Hysterectomy should be done whenever peritonitis is present in the course of puerperal fever. 7. Hysterectomy should be performed in cases of puerperal mania where there is a history of endometritis without uræmia. 8. Hysterectomy may not be helpful in the course of diphtheritic vaginitis and endometritis. 9. Hysterectomy may not be helpful in cases of rapid early infection. 10. It may not be useful in cases of septic phlebitis reaching outside the pelvis.

A Method of Preventing Thirst Following Celiotomy.—Dr. William H. Humiston read a paper with this title. He said no one who has had any experience in the after care of abdominal cases will deny the important place that thirst occupies. It is the one prominent, annoying, and distressing symptom, and I know it can be overcome. This is my method of procedure:

The patient should have the usual preparation for celiotomy, *i.e.*, diet, daily baths, cathartics, etc. For three days prior to operation order the patient to drink one pint of hot water an hour before each meal and on retiring, thus drinking two quarts of water each twenty-four hours, the last pint to be taken three hours before the time set for operating. Do not omit to give the water the day previous to the operation, while the patient is restricted to a limited amount of liquid nourishment and the bowels are being unloaded. We thus restore to the system the large loss of fluid occasioned by the free catharsis, and we have the great satisfaction of seeing our patient pass through the trying ordeal of the first thirty-six hours after the operation in comparative comfort, with no thirst, a moist tongue, and an active renal function, represented by an excretion of from twenty-eight to fifty fluid ounces of urine during the first twenty-four hours, catheterization being seldom necessary. This is in keeping with the full character of the pulse noted.

The above detail I have recently carried out in twelve cases. To eleven chloroform was administered, to one, ether. The time required to complete the operation varied from ten to fifty-five minutes. Whether the case was one of sclerotic ovaries or a pus case with universal adhesion of all the pelvic structures, the result has been uniform and highly satisfactory, thirst being allayed and excretion stimulated.

I believe this method will prove to be efficient in the hands of abdominal surgeons generally, and I publish it early with all confidence that the twelve cases that I have had will soon be fortified by the reports of many hundreds, and that by it we may avoid a condition that is and has been distressing alike to the patient, surgeon, and nurse.

Celiotomy in General Suppurative Peritonitis, with the Report of a Case.—This paper was read by Dr. Miles F. Porter, of Fort Wayne, Ind. The author first quoted Grandin, who says regarding general puerperal peritonitis: "The women die, no matter what the form of treatment employed." Dr. Baldy says: "To my knowledge there has never been reported an undoubted case of general purulent peritonitis, from any cause whatever, in which an abdominal section or any other line of treatment has succeeded in saving the patient's life." That the mortality of general septic peritonitis is large, all will agree, but that it is always fatal is certainly not true. Dr. Porter then reported the case, and closed by saying that the object in writing the paper was to assist in arousing a sentiment against the too prevalent idea that in general septic peritonitis death is inevitable, and to encourage in these cases prompt operative interference.

Peritoneal Irrigation and Drainage was the title of a paper read by Dr. A. H. Cordier, of Kansas City, Mo., in which he said that the latest works on abdominal and pelvic surgery contain, like the older text-books, very short and misleading articles on the indications for peritoneal irrigation and drainage, and still less explicit are the directions how to use these agents for good, intelligently and correctly. This diversity of opinion among authors leaves the inexperienced beginner in a position of perplexity and doubt as to the special course he is to pursue in his early work. The same principles hold good in draining the peritoneal cavity that are applicable to other parts of the body. No surgeon with all the antiseptic precautions possible to be used in opening a diffuse abscess of the thigh or other part of the body would think of such a thing as at once closing a wound hermetically, leaving many broken-down shreds of diseased tissue dangling in the abscess cavity. He might have irrigated the cavity thoroughly with a 1 to 1,000 solution, yet he would not feel it safe to close the wound until after he had made counter-openings and introduced a drainage-tube, this

being as near ideal surgery as it is possible to obtain in these cases. Freshly boiled distilled or filtered water, cooled to 102° to 110° F., should be used in irrigating.

The author drew the following deductions: 1. Drainage is a life saving process when properly used. 2. To use it is not an admission on the part of the surgeon that his work during the operation is imperfect. 3. The use of the tube alone does not produce or leave any condition that favors the development of hernia. 4. The omentum or other structures do not become entangled in the openings in the tube. 5. A small-sized flint-glass tube, with small openings and open end, should always be selected for pelvic drainage. 6. The tube does not produce fecal fistula. 7. The tube should be used when in doubt as to the absence or presence of drainage indications. 8. To depend upon microscopic findings as to whether a given case should or should not be drained is seemingly scientific, but is neither necessary nor practicable. 9. Gauze drains should rarely be used and should always be supplemented by a glass drain. 10. There is no danger of infecting the patient through a tube if the attendant is properly instructed.

Three Cases of Hysterectomy following Celiotomy for Pus-Tubes.—Dr. J. Henry Carstens, of Detroit, summarized his remarks as follows: "1. It seems to me, in the light of my present experience in cases of bilateral pus-tubes, that a more perfect and complete operation can be performed by abdominal section, with less danger of injury to the bladder and intestines, and with smaller mortality and better ultimate results. 2. That in certain cases a better immediate result is obtained by vaginal hysterectomy and drainage, but these cases frequently require a second operation to remove the ovarian tissue and parts of the tube, which at first in many cases cannot be removed, before a perfect ultimate cure is established. 3. Where the sympathetic and other nerves are affected, the cause is not in the uterus, ovaries, or tubes alone, but part in each. We are unable to state which organ is at the bottom of the trouble. Sometimes it may be only one, sometimes the other, sometimes two or all three; hence, in such cases—I would say in many cases—with marked nervous symptoms, the best results are obtained only after the complete removal of every particle of the generative organs—that is, uterus, tubes, and ovaries, be this accomplished at one, two, or three operations, per vagina or by abdominal section."

Dr. R. S. Sutton, of Pittsburgh, favored abdominal section for pus-tubes. He maintained, first and foremost, that a uterus deprived of its appendages is of no use. Second, that it is an organ, if left, which is liable to tuberculosis, gonorrhœa, syphilis, nasty discharges, adhesions, etc. When it is decided to remove the appendages, the uterus also should be taken out.

Dr. Gilliam of Columbus, O., argued against the removal of the uterus with the appendages in order to save life, the objection being that shortening of the vagina resulted.

Dr. B. M. Ricketts, of Cincinnati, believes total extirpation will be relegated. The dangers are cystocele, hernia, increased danger of prolonging the operation, and shortening of the vagina.

Dr. Henry O. Marcy, of Boston, favored retaining the cervix when it is healthy, and pointed out the reasons why it should not be removed. It helped materially in acting as a support to the vault of the vagina.

Dr. Holmes, of Chicago, in discussing Dr. Cordier's paper, said that drainage was a sort of vicarious redemption for poor surgery. Whenever it is impossible to make a wound clean we must drain, and sometimes we drain when the wound is clean, but we are unable to arrest the hemorrhage. He could conceive of no other indication for drainage, whether in the abdomen, the brain, or any other part of the body, than failure to meet the one great indication of wound treatment—to keep the wound clean.

Two Successful Operations for Traumatic Insanity.—Dr. George W. Cale, of St. Louis, read the paper. He said that insanity due to injuries of the head is of rather infrequent occurrence. In 2,200 cases of insanity treated by Kiernan, 45 were of traumatic origin; while Hays records 61 due to the same causes out of 2,500 cases. Schlager reports 500 cases of insanity due to concussion of the brain. The author then considered the causes and symptoms.

Case I.—A male, twenty-six years of age, carpenter by occupation. Family history good. No case of insanity or of serious nervous disease had ever been present. June, 1885, the patient received a blow from a club in the hands of a negro, the wound inflicted being midway between the fissure of Rolando and the external occipital protuberance, slightly to the left of the median line. It was treated as an ordinary scalp wound, as it suppurated for three months. Four years after the inception of the wound he complained of severe pain in the left parietal and occipital regions of the head. October, 1888, he was sent to an insane asylum, where he remained sixteen months. His condition improved, he returned home, but was again sent back to the asylum, where he was detained five months. Four months later he was brought to Dr. Cale, who diagnosed traumatic insanity, advised operation, which was consented to. Recovery.

Case II.—One of acute mania following trauma. Operation performed the same as in Case I. Recovery.

Dr. William Fuller, of Grand Rapids, Mich., had operated on two cases of insanity, due to traumatism, one in Montreal in 1870. The patient was discharged from an insane asylum as incurable. When the dura mater was opened there escaped some serum. A few days subsequent to the operation the patient was rational, but as soon as the wound closed up the hallucinations returned. He then punctured the brain in two or three different directions, but with no result except to establish drainage. The man died two months later, and a post-mortem examination revealed a tubercular abscess in the fissure of Sylvius, containing about two teaspoonfuls of pus. The other case was due to syphilis, and was relieved by the removal of the pressure from that disease.

Dr. J. Frank, of Chicago, reported an interesting case of insanity in which he trephined, removing a large piece of bone. A piece of the brain was also excised for examination and seemed to be healthy. The patient, after being in an insane asylum for five years, made a complete recovery, and took up the thread of life where she left it. She continued in this way for one year, then relapsed. What was the reason of her recovery? In opening the dura there was a gush of cerebral fluid. Dr. Frank firmly believes that it is not the depression of the skull which produces the bad results, but that at the time of the injury there is a chronic inflammation of the meninges, or a slow inflammatory process, which throws out cerebral fluid. This fluid may be in the ventricles between the dura and the brain, or in the tissues of the brain-filaments themselves, and the theory of concussion, held by the profession, he believes is erroneous. He had repeatedly made experiments on dogs by rapping them on the head and rendering them insensible, and immediately thereafter effusion was found.

Dr. F. Maas, of Detroit, thought we were in the dark as to the exact cause of the insanity in many cases, and that there was evidently some vaso motor disturbance. He read a paper, which was largely a statistical one, in which he pointed out the comparative value of the medical and surgical treatment of appendicitis.

The Use of Dry Heat of High Temperature in the Treatment of Joint Diseases.—This paper was read by Dr. William E. Wirt, of Cleveland, O. Shortly after reading a description of this treatment in the medical

journals, the essayist encountered a case of rheumatoid arthritis in which he resorted to this method. The treatment was followed by great improvement in the motion of the joint and in the comfort felt by the patient. He also reported a case of rheumatism of a year's standing in which there was more or less fixation. He broke up the adhesions, made use of the high application of heat, and raised the temperature to 290°, which was followed by decided improvement in the ease with which the patient could move the joint and the relief of pain.

Ulcers of the Leg; all can be Cured.—This paper was read by Dr. Carter S. Cole, of New York. The constitutional condition of pain that favors morbid states, or that retards a return to a healthy state, creates a diathesis which should receive its proper treatment, whether or not ulcers exist. For systematic purposes ulcers of the leg were designated by the author according to their appearance, as healthy, irritable, indolent, etc. In intractable cases, he is inclined to place foremost thorough washing with soap and water and good scrubbing with a stiff bristle hair-brush. If the ulcer be inflamed, irritable, or painful, anæsthesia may be required for this and subsequent steps. The next step is a thorough cleaning out of all soft granulations and the base of the ulcer with a sharp curette. The edges of the ulcer are freed from their attachment, and in many cases with a curved sharp bistoury he knicks the circumference at intervals of about one-quarter of an inch. If much hemorrhage follows, a pad of gauze wrung out of a two per cent. solution of carbolic acid is placed over the wound and a firm compression bandage from the toes to the knee applied, the wound having previously been thoroughly cleansed with the carbolic solution. The dressing, when used, is allowed to remain for twenty-four or forty-eight hours, after which he considers the ulcer to have become a simple one and amenable to treatment as follows: No further lotion is used. The wound is wiped off with dry cotton, and over and completely covering it he places strips of diachylon plaster to protect the ulcer. Over the surgeon's plaster he applies a pad of sterilized gauze, held in place by strips of rubber adhesive plaster, or often simply by a bandage. He then uses a firm muslin bandage from the toes to the knee, making equable compression. Bandaging should be carefully done. Sometimes he uses two bandages three inches wide and eight yards long. This bandage is not removed unless the discharge comes through, or the leg becomes painful, or the bandage gets loose. When he redresses the ulcer he again uses simply dry absorbent cotton to cleanse the wound and proceeds as before. Often after two to three dressings the bandage may remain five or seven days without being disturbed. In some cases a thin scum forms on the ulcer, which must be removed by going over the surface lightly with a curette. With this treatment, in ordinary cases about three weeks will suffice for an ulcer of even a dozen years' standing. In extraordinary cases, as much as six weeks may be necessary.

How to Diagnosticate Sexual Derangements in the Male, was the title of a paper by Dr. Eugene Fuller, of New York City. The author endeavors to impress on the profession the fact that in the majority of instances sexual derangements in the male are caused by pathological processes in or about the seminal vesicles, and further, that they accomplish their results by interfering with the mechanism of ejaculation. He calls attention also to the fact that this side of the question has almost wholly been neglected by preceding writers on sexual disorders, who have devoted themselves largely to psychological causes in this connection, the result being that the great majority of the profession associate sexual disturbances with some radical mental defect. Sexual derangements in the male should be diagnostically arranged in four classes: 1, Those dependent on seminal vesiculitis; 2, those dependent on neuroses; 3, those dependent upon primary mental disease or degeneration; 4, those dependent on general malnutrition and debility. The order of this classification corresponds to the frequency with which these different forms of diseases are encountered in practice. In explanation of the first class of causes the writer states that it is needless to go into detail, since he has recently reviewed that subject very fully in his book just published.

Where seminal vesiculitis exists there is generally a previous history of urethral or bladder inflammation, sexual abuse, and the like, all of which are agents tending to produce localized inflammation in the seminal vesicles. The second class of causes either inhibit or excite the sexual centre by means of reflex nervous action. The third class of causes includes the different forms of paranoia, in which the sexual sense exists in a perverted form. The fourth class of causes is a small one. It includes individuals, generally young or middle aged, who make complaint that they are capable of little sexual exertion and that feelings of prostration and exhaustion result whenever coitus is attempted.

Dr. Fuller then takes up the clinical examination. In conclusion the writer makes some special remarks on the different appearances that the varying grades of seminal vesiculitis present to the sense of touch, and calls attention to the fact that in cases of extensive perivesiculitis involving both sacs an inexperienced examiner is liable to err in diagnosis, mistaking the condition for hypertrophy or inflammation of the prostate. The author holds that to become perfected in the feel of the seminal vesicles the finger needs as much practice as does that of the gynecologist in feeling the ovaries and tubes. To obtain the necessary practice he advises the genito-urinary surgeon to make it customary to examine in this manner every male case coming into the clinic until all normal and pathological conditions can be fully appreciated.

Chronic Seminal Vesiculitis with Hemorrhage.—Dr. S. P. Collings, of Hot Springs, Ark., read a paper on this subject, in which he said there has apparently been little known of the pathological conditions of the seminal vesicles until within recent years. The usual cause of this trouble is the extension of gonorrhœal inflammation from the prostatic urethra through the ejaculatory duct into the vesicle itself; at least, there is usually a history of a former gonorrhœa with a chronic deep urethral trouble remaining. The vesicles are sometimes involved in very acute and severe gonorrhœal inflammation with or without the implication of the cord and epididymis. They may also be involved with a tubercular inflammation, although practically never primarily.

One observer reports a case in which the autopsy showed that the vesicle was primarily involved. The most important symptom is the disturbance of the sexual function. The character and appearance of the seminal fluid are more or less changed. Its consistency is so increased at times that it is gelatinous. The diagnosis of subacute or chronic seminal vesiculitis would be difficult to make were we to depend entirely upon symptoms in reaching a conclusion. They are vague and at times misleading, except the appearance of the blood in the semen, which, if thoroughly mixed with it, would determine a diseased condition of one or both vesicles at once. The author reported two cases, discussed the treatment as applied to them, as well as that generally used in the subacute and chronic forms.

In conclusion, he said that if inflammation of the vesicles occurs in one whose urethra is strictured, we must cure the stricture before we can hope for permanent results in vesical treatment.

Syphilis and its Treatment.—This paper was contributed by Dr. C. T. Drennen, of Hot Springs, Ark. The author spoke more directly of the treatment of this disease in connection with the use and abuse of certain so-called antisyphilitic remedies. He said we are unable as yet to form definite conclusions as to the

usefulness of sero-therapy in the treatment of syphilis from the most recent researches. But the reports are quite encouraging, and there is hardly a doubt but that it possesses value in at least the tertiary lesions. Fournier believes the good effect to be due not to any specific, but to its rehabilitory effect upon the system. The author said, in closing, that the hot water at Hot Springs was well known to exert an influence peculiar in its effect for good, and in it we had a veritable Mecca for syphilis. That its action is eliminative, stimulative, and antiseptic, and that larger doses of mercury and the iodide of potassium can be given without harm is known to the writer based upon experience and observation; that its exact or specific action is unknown, and that its value is attested to by the multiplied thousands throughout the country, are propositions that are uncontrovertible.

Dr. William T. Belfield, of Chicago, described and presented an instrument for the purpose of securing asepsis in bladder and prostate operations.

The Element of Vascular Compresson in Fracture Treatment.—This paper was read by Dr. Thomas H. Manley, of New York City. The author considered at length the anatomical structure and vascular function as related to fracture. The extent of damage borne by the vessels in a given case of fracture will primarily depend upon the degree and quality of force applied and the line of treatment adopted. In a series of experiments made during the past year on the blood and blood-vessels, under a multiplicity of conditions in the lower animals under anæsthetics, one question which the author spared no pains to definitely determine was whether in fracture, as a general rule, the circulation to the distal part of the limb was retarded in cases of fracture. Without entering into detail on the great diversity of vascular phenomena observed in a frog's webbing under the microscope after single, multiple, and compound fractures were produced, it will suffice to say that with few exceptions, immediately and for a considerable period of time after the bone was broken, the circulation in the capillaries and the smaller arteries was completely arrested. In several it was found that for several days all the smaller vessels were motionless, and in a few they so remained until the fractured ends of the bones united. These experiments were extended to the mammalia—the shafts of the limbs of pups, kittens, and adult dogs, of different ages and of various sizes.

The Significance of Fissure Fractures of the Articular Ends of the Long Bones was the title of a paper read by Dr. H. O. Pantzer, of Indianapolis, Ind. He reported a case of fissure fracture involving the outer third of the head of the radius, having loose attachments to its body. An excessive callus had likewise developed in its site, without affecting union. This splinter and callus were removed, when reposition of the joint was easily attained. The crepitus felt at the first examination, and the failure to find it again, should have suggested fissure fraction in the opinion of the author. When the first dressing was removed, the limb seemed to present a perfect condition, and to promise full restoration. These prospects were changed as soon as passive and active mobilization was begun. The probability is that the attempts at mobilization for this kind of injury were made too soon, and that they were at least partially responsible for the subsequent unfavorable developments. The author concludes that when undue painfulness and subsequent swelling with no gain, or even a loss of mobility, attends the efforts of mobilization after kindred lesions, we should delay further efforts at mobilization. The possibility of a fissure fracture should be considered in determining the diagnosis and treatment of all cases of joint injury.

Imbrication or Lap-joint Method—A Plastic Operation for Hernia.—Dr. E. W. Andrews, of Chicago, contributed a paper on this subject. The principle of imbrication or overlapping the several aponeurotic layers of the abdominal wall may enter into other abdominal operations to advantage, as he had repeatedly shown. The present paper referred only to its use in inguinal hernia. Here he makes use of it to supplement and reinforce existing methods without losing sight of their good qualities. While based upon the best modern open method, and while confessedly an outgrowth experience with the Macewen, Bassini, Halsted, and similar operations, yet the carrying out of the imbrication idea so far changes the technique as to make it as different from them all as they are from each other, and perhaps entitle it to the term, "a new operation." It was impossible, said the author, to describe this operation without going into details concerning those which had preceded it, which he did.

The interlocking or overlapping principle of uniting the musculo-aponeurotic layers of the abdomen is in reality an outgrowth of the author's clinical experience rather than of theory. He adopted it at first as an expedient in cases where the Bassini operation seemed difficult and needed supplementing, but of late the value of the principle had seemed to him more and more evident, and he had used it in all his cases. The author concluded as follows: 1. Any successful method of radical cure must be a true plastic operation upon the musculo-aponeurotic layers of the abdominal wall. Cicatricial tissue and peritoneal exudates are of no permanent value. 2. A large strong flap, of any needed size, to fill the internal ring. 3. Triplicate layers of aponeuroses. 4. Interlocking of layers giving broad surfaces of union. 5. Shortening of anterior as well as posterior wall of canal, making them mutually supporting, and relieving tension on deep sutures. 6 Cord amply protected.

Further Observations on the Radical Cure of Rupture by the Intra-pelvic Method, with Illustrative Cases.—This paper was read by Dr. Charles A. L. Reed, of Cincinnati. In what essential particulars does this intra-pelvic method differ from the several methods of radical operation now in vogue? It differs, in the first instance, in the fact that it is intra-pelvic, while the others—Bassini's, Halsted's, McBurney's, Macewen's—are extra-pelvic.

The essential point of difference between Dr. Reed's operation and that of Bassini consists in: 1. Leaving undisturbed the extremely tense fascia composing the anterior wall of the ring. 2. In leaving the cord in the position which nature designed for it, and entirely protected by the normal fascia. 3. In closing the internal ring on the inside of the pelvis, and in protecting it by a strong peritoneal pad. 4. In avoiding the menace to virility arising from a transplantation of the cord, its possible constriction by an artificial ring of tense fascia, and its necessary investment by an inflammatory exudate. 5. In increasing the resistance of the parts by fortifying the fascia comprising the anterior wall of the ring, and by increasing and making permanent the obliquity of the cord within its normal canal.

The advantages of the operation consist in securing, by the unfolding of the redundant but attenuated median fascia, the formation of a column which, when consolidated by inflammatory adhesions, has a certain retentive and supportive power, the influence of which is of value in preventing recurrence. The anchorage of the recti in the median line destroys the retentive power of the wall.

Surgical Treatment of Hemorrhoids.—Dr. Henry O. Marcy, of Boston, followed with a paper which was in the nature of a reply to the strictures cast upon the Whitehead operation by Dr. Edmund Andrews, of Chicago, in a paper read before the last meeting of the Illinois State Medical Society. Dr. Marcy believes that if, in the statistics given by Dr. Andrews, the names of the operators were mentioned, most of the disastrous results would be found to have followed the

work of incompetent men. His results have been excellent in those cases in which he has done the Whitehead operation, slightly modified by himself.

Club-foot.—Dr. John Ridlon, of Chicago, read a paper on club-foot, which he defined as a distortion of the foot in its relation to the leg. The simple and compound varieties of club-foot were dealt with. Nearly all of the congenital cases present the compound variety—equino-varus; a few present equino-valgus; rarely there is seen a simple calcaneus. Of simple equinus the author had met with but a single instance, and of simple varus and simple valgus he had seen none. Of the acquired variety, simple equinus is by far the more frequently found; next in frequency we find simple valgus; then equino-varus, calcaneo-valgus, equino-valgus, simple varus, and varus in one foot, and valgus in the other. The acquired deformity occurs more than three times as frequently as the congenital form. The etiology of the congenital forms was next dealt with, as well as of the acquired forms. Then followed the symptoms, diagnosis and prognosis.

The treatment of club-foot is mechanical or operative, or both mechanical and operative. Both these measures were dealt with at length.

Vaginal Castration.—This paper was read by Dr. E. E. Tull, of New York. The author claimed for this method a lower mortality, a shorter convalescence, and a wider adaptability, as it may be practised in cases too weak for abdominal section.

A New Phase of Celiotomy.—Dr. F. G. Groner, of Grand Rapids, Mich., related a suit for malpractice which had just been terminated in Grand Rapids. The suit was commenced against a doctor some time ago, and was for $50,000. The defendant died, but the court held that the cause of action survived, and that the suit could be brought against the estate. The jury returned a verdict for $10,000. The author claimed that he knew there was no malpractice, because he was interested in the case and knew just what was done in the operation. He found fault with the laws which permitted a suit against the doctor to survive his death and be a menace to the widow and children. The speaker thought that the next Legislature should remedy the law. He had the draft of a bill prepared which he thought would remedy the present law, and which he read.

The Results of Five Years' Experience with Intra-abdominal Shortening of the Round Ligaments.—This paper was contributed by Dr. J. Frank, of Chicago. Since his last publication, November, 1889, he had had the opportunity of performing this operation seventeen times, with only one failure, and without any deaths. All of the seventeen cases operated upon were for retroversion, prolapsus, and retroversion with prolapsus of the uterus.

Technique of the Operation.—The median incision is made a trifle lower than for ordinary celiotomy. The round ligament is caught up anteriorly with a sharp or blunt hook, and is then held taut by an assistant. A small, full-curved needle threaded with fine silk is then passed through the loop of the round ligament, and is brought back in the reverse manner through the other half of the loop. No portion of the broad ligament is included in any of the sutures. Too much stress cannot be placed upon this particular procedure of passing the needle through a part of the cord, and not around it, for in passing the needle around the cord there is danger of strangulation, as the blood and nerve supply would be entirely shut off by this faulty method of placing the sutures around the ligament.

About fifty per cent. of the cases have been under the observation of the author since the time of operation, which in some instances has been as long as two years, and in all of these the uterus retains its corrected position. This operation should be performed in preference to any other in all cases where the uterus is prolapsed, or immediately falls back upon replacing it with a uterine sound, and where pessaries and tampons afford no relief, clearly showing that there must be some force which does not permit the uterus to remain in its normal position.

Address on Surgery.—Dr. Theodore A. McGraw, of Detroit, selected for his subject "The Present State of Our Knowledge of Cancers and Tumors." He said that if we compare the ideas that prevailed relative to these diseases thirty years ago with those the profession hold to-day, we would find a change which marks rather by a clearer view of the nature of the problem than any actual gain in its solution. Before Virchow the subject of tumors and cancers was wrapped in the greatest confusion. Tumors were divided and classified in that era according to their clinical histories. They were divided into the innocent, which were looked upon as purely local, and the malignant, which were regarded as due to dyscrasiæ, the seat of which is in the blood. Under the influence of the new cellular pathology the faith in so-called dyscrasiæ was abandoned and supplanted by a new doctrine, which taught that tumors and cancers resulted ever and always from aberrations in cellular nutrition, development, and growth. It may be said that during this time the energies of the profession, as far as tumors are concerned, have been confined almost solely to this channel. The most successful attempt to account for the origin of tumors and cancers was that of Cohnheim.

The arguments offered in defence of the parasitic theory of cancer are, 1, the microscopic evidences; 2, the frequent occurrence of auto-inoculation, and the evidently infectious course of the disease in the organism; 3, the endemic occurrence of cancer in certain localities, and in rare instances in the same houses; 4, an occasional success in inoculating the disease in animals. The arguments against it are the many instances of hereditary tendency; the general failure of experiments of inoculation, and the fact that metastases occur, not through the transfer from one point to another of parasitic germs as is usual in parasitic diseases, but by the transmigration of cells bearing the same characters as the cells of the original tumor, and the subsequent proliferation of the migrating cells; the fact that not only cancers, but tumors of all kinds, have a more or less tendency to produce metastases; the tendency exhibited by embryonic remains and hystoid tumors to develop into malignant disease.

Dr. McGraw closed by saying that physicians should be better instructed in the means of diagnosis, and in the necessity of early operative treatment. And last, but not least, the laity could be induced to assist, not only by liberal contributions of means, but by that intelligent co-operation which would lessen our difficulty in collecting evidence and making post-mortems and keeping the sufferers out of the hands of the quacks.

The Paranoiac—A Menace to Society.—This paper was read by Dr. C. B. Burr, of Flint, Mich. He made brief and pointed reference to the numerous recent murders of prominent persons by so-called "cranks." What to do with these persons is one of the problems confronting our modern civilization, and is one demanding an answer from students of the subject. We have room enough in our asylums. The trouble is that harmless lunatics are kept in confinement, while dangerous paranoiacs are allowed their liberty. These murders disturb the public but a day and do not scare us into further provision for a safeguard. The public do not sincerely seek advice from professional sources in the matter. No one who has been threatened by a paranoiac would be willing to have his commitment settled by a jury without medical testimony as to the danger involved in granting freedom to such an individual. The paranoiac is a menace to society, and should be sequestrated. But doubtless the public will continue to view with indifference or approval, now and then, the execution of a criminally insane person as "sane

enough to hang," and vainly hope for a deterrent effect of this example upon other deluded minds.

Dr. I. N. Love, of St. Louis, remarked that doubtless all of us would hesitate to offer criticism on so valuable and thorough a paper from such an authority as Dr. Burr. He then related a case in St. Louis, where a man had murdered his wife and child, having become a paranoiac through excesses and debauchery. The entire profession of St. Louis agreed that it was the deed of a paranoiac, yet a country jury declared he was sane enough to hang. He emphasized the fact that often these persons are stimulated to crime by the notoriety the newspapers give them, and consequently the papers should be encouraged to suppress any such items.

Dr. Hugh T. Patrick, of Chicago, called attention to the fact that the fixed illusions began as early in life as five or eight years, and then in such cases measures of restraint should be instituted. These illusions are not always discovered, even by the family physician.

Toxicity in Hysteria, Epilepsy, and Neurasthenia, was the title of a paper by Dr. A. E. Sterne, of Indianapolis. This is one of the most frequent and important etiological factors in these diseases, and one which has received the least attention. The term toxicity should mean functional cellular perversion, causing or being caused by abnormal chemical reactions. The ordinary forms of hysteria are functional. There are, however, no pathologic alterations in the central nervous system itself. We have in many cases a condition of cellular intoxication. It is not necessary that there be any structural change. Many drugs produce a condition similar to hysteria; shock or injury does the same thing. In almost every case there will be some form of cellular malnutrition, and by not seeking after this possibly the physician misses the cause and cure of his case. The female generative organs have, no doubt, been too often blamed as an etiological factor in hysteria. When actual disease exists in these organs it should be properly attended to, but the organs are not to be blamed any more frequently than other organs. Again, some of the worst cases of hysteria occur in males. Epilepsy, like hysteria, is a diathesis, but of a more profound nature, but in epilepsy we find true pathological changes which are usually of a vascular nature, in the walls of the vessels, produced by some toxic agent, acting at the same time on the ganglionic cells of the cortex. The attacks of epilepsy may resemble severe hysteria, but there is a fundamental difference. The attacks of the latter are never dangerous, while the former may frequently be so. Neurasthenia is not often complicated by either epilepsy or hysteria. There are three grades of neurasthenia—weakness, prostration, and exhaustion. Sexual neurasthenia is essentially a masculine affection, though not always or necessarily resulting from a vicious life. In the treatment of all these cases the toxic element should always be kept in mind. In certain cases surgical interference is demanded. Change of scene and environment are the best treatment for hysteria and neurasthenia. Divert the energies into other channels; conserve the remaining vital forces, and add suggestive therapy as much as possible, but do not hypnotize. The wakeful state is much better for suggestion. Electricity and the "rest-cure" play an important part in the treatment of all these conditions. But always conserve every atom of nerve-force in every case.

Dr. Blech, of Detroit, reported two cases in which he considered there was toxicity of cellular function.

Dr. Dougherty, of South Bend, Ind., said it should be remembered that these cases do not all come as reflexes of the generative organs. It has become almost a habit for surgeons and physicians to think so.

Dr. C. B. Parker, of Cleveland, said that more care in diagnosis and a deeper investigation into the etiology of these cases might materially assist us in the way of results in treatment.

Dr. Hugh T. Patrick, of Chicago, held that traumatic cases must be excluded from this consideration. They come under another class, such as adhesions, etc. He is quite sure that very many of these cases are due to a direct toxæmia. Indeed, all conditions which may cause any functional derangement are in a measure toxic.

Dr. Sterne, in closing, said he was convinced that the knife was being used too much in these cases. If we can be sure of the lesion, then certainly operate, if it is advisable. Relative to the thyroid enlargement, he is satisfied that there are very many cases of it in hysteria, particularly if the patient be a young lady.

Some of the More Recent Methods of Staining Nerve-Tissue.—This paper was read by Dr. Hugh T. Patrick, of Chicago. It was elegantly illustrated with water-color drawings of each of the stains used in nerve-tissue, and a most thorough and practical *résumé* of the subject, with its application and technique, was given. He considered the method of Nissl to be the method *par excellence* for nerve-cells. With it minute changes in the cell-structure could be detected which would elude any other method. The method of Bevan Lewis, while marking an advance in technique, was thought to be less perfect than claimed for it by the originator. It is, however, excellent for hypertrophied neuroglia cells. The beautiful results obtained by the Golgi method, as modified by Ramon y Cajal, were illustrated, and the importance of the discoveries due to it were emphasized. Rosin's stain, which is practically the Ehrlich-Biondi blood-stain, gives in some cases almost ideal results. The method of Platner—chloride of iron and diniero-resorcin—was illustrated as applied to normal and degenerated nerve-fibres, and the doctor thought the method was to have an important future. The method of Marchi was said to excel any other for degeneration of from three weeks to three months duration. Allusion was also made to the developmental method of Flechsig, and to an unusual but valuable result of the Weigert-Pal stain and illustrated drawings shown.

Dr. Sterne said that the carmine stain has a particular adaptability for double staining. In bringing out the anatomical details it is practically a necessity. The Nissl stain is the most exact, and for giving an idea of the ganglionic structure cannot be excelled. For all purposes the Marchi method is perhaps the most reliable.

Dr. Patrick said he had simply pointed out the advantages of each method. We want for each case that which will give us the best results.

Psychology in Medicine, by Dr. A. P. Buchman, of Fort Wayne, Ind. The author discussed the subjective and objective relations of mind and pathological conditions. The unit force acting properly is health; abnormal action of this unit is disease. The structure of man is governed by a connected train of associated movements called ether, the existence of which we can have no anatomical proof; but to which the growth of the body must bear definite relation. Fear, grief, anger, or joy modify the functions of the vital centres. The sympathetic nervous system is the centre of the emotions, and the cerebro-spinal system that of abstraction. Thus we come to psycho-physiology and bio-chemistry. Thence we step to the subject of hypnotism. The different methods used in producing hypnotism were minutely described; then the possible uses and dangers of hypnotism in medicine were discussed, showing that, while good might be done, there was also much danger in its use.

Dr. Sterne said it was giving to the hypnotizer a dangerous power. Anyone can hypnotize, as only a certain mental concentration is necessary. The interest in the subject is not so much a medical as scientific one. There is frequently, if not always, an element of fraud in hypnotism. There is a chance of murderers claiming they were hypnotized.

Dr. Patrick emphasized the fact that the hypnotizer has no hypnotic power. It seems almost a farce to discourage this idea, as it was exploded a century ago. It is purely a subjective influence.

Dr. Burr remarked that the insane could not frequently be hypnotized. They could if the hypnotizer had any power in reality. It is possible in epilepsy to do much with it; also in hypochondriasis and melancholia it might be valuable.

Dr. Buchman claimed the French Academy had in the past ten years positively demonstrated the existence of hypnotic power.

Dr. Patrick said, in rebuttal, he did not claim that there was no such thing as hypnotism, but that the hypnotizer had no direct power in himself over the subject hypnotized.

The Nervous System as a Factor in Disease.—Dr. C. J. Helm, of Peru, Ind., then presented a paper on this subject. It was an excellent *résumé* of a great subject, and to make a notice of the points made without free excerpts is impossible. Slight functional disturbances, if constant and continued, may produce actual organic lesions. Change is the great remedy for these troubles, not necessarily of surroundings, but of the waste places in the nervous system; give the forces some new direction. Study your patient in every phase. Get them out of the ruts they have gotten into, and you will have then cured your patients before you know it.

Some Considerations with Regard to the Senile Heart.—By Robert H. Babcock, of Chicago. The condition is not always due to or necessarily found in the aged. Importance should always be given to the myocardial changes. Dyspnœa is a most frequent symptom of senile heart, although it occurs in other conditions as well. It finally becomes the almost surely fatal symptom — Cheyne-Stokes respiration. Various remedies were advised, and among them the hypodermic use of morphia in a single dose.

Dr. Fütterer, of Chicago, said we sometimes find in these cases a more or less intermittent pulse.

Dr. J. B. Herrick, of Chicago, added his testimony with regard to arythmia, which he considers a frequent and most important symptom.

Dr. Babcock said that the intermittence is not necessarily a dangerous symptom, but at the same time any such senile heart is liable to stop during one of these diastolic irregularities coming on suddenly. In Cheyne-Stokes respiration morphia seemed to act best with small doses of atropine.

Dr. Frank Billings, of Chicago, presented a paper on "Intercostal Neuralgia." The disease is always secondary and consequently, in reality, only a symptom. It may be due to toxic forms of functional nerve disturbance, or to pressure by tumors. The functional form is most common and usually due to a toxæmia, or to a defective excretion or malassimilation. Indigestion is a most frequent factor, whether due to the character of food ingested or to nervous conditions. Insufficient food and lack of outdoor exercise are frequent causes. Intercostal neuralgia occurs oftener in females, usually on the left side. Palpitation is usually present. Gas in the stomach with eructation is always present. In diagnosis we must search for the cause. It may be confounded with pleurisy or muscular cardiac rheumatism. In treatment remove the cause and give any simple restorative tonic.

Dr. W. H. Porter, of New York, read a very exhaustive paper entitled "New Light on the Rôle which Iron Plays in the Physiological Economy—How and where Does the Hæmoglobin Come from?" It is not the product of synthesis. It is difficult to formulate a nucleo-albumin. The iron is not excreted by the salivary, gastric, or sweat glands. The hair uses up some, the urine a slight amount. The bile uses most, but the total in both hair and bile is only one-tenth grain daily. Some writers say that the iron is stored up in the liver, but this is not practical. The intake and output both being very small, we must conclude that iron in the body is very stable. There is then a question, whether iron should be so frequently and indiscriminately used in anæmia.

Dr. John North, of Toledo, had almost given up the administration of iron in cases of anæmia. In most cases we should correct the trouble in the alimentary canal, avoid the destruction of the nucleo-albumins, and no iron will be needed.

The Abortive Treatment of Typhoid Fever.—The paper of Dr. John Aulde, of Philadelphia, was read by the Secretary of the Section. The author reviewed the advantages of guaiacol, carbolic acid, salol, betanaphthol, and others, and finally gave his own and others experience with arsenite of copper, stating that in his opinion the disease could be aborted at almost any stage by the use of copper arsenite along with appropriate constitutional remedies. As a rule $\frac{1}{100}$ grain should be given every four or six hours. The remedy may be given hypodermically if the disease be advanced to the second or third week.

Medicinal Treatment of Typhoid Fever.—This was a paper read by Dr. Gustav Blech, of Detroit. The author opened his paper with, "There is no Specific Treatment for Typhoid Fever." Hydrozone, 1 to 32, is a most valuable intestinal antiseptic. Irrigation of bowels with cold water is a necessary adjuvant in all cases.

The two preceding papers, along with that of Dr. J. E. Woodbridge, of Youngstown, O., on "Typhoid Fever and its Abortive Treatment," were read in succession and discussed jointly.

Dr. Love said the treatment suggested by Dr. Woodbridge was not original; that all physicians had used the same for years. He protested against the use of the term abort, as he thought it could not be done. Rest is an important factor in the treatment. Typhoid fever is a matter of diagnosis. He questioned the diagnosis of typhoid in some of the cases reported by Dr. Woodbridge.

Dr. North would change the word abort to miscarriage. The germs do not enter the circulation. If we can discover something which will eliminate the germs, we can thus cut short the attack. The constant study of the one disease is the only way to progress. He does not think one can become too enthusiastic, but conclusions can be drawn too hastily.

Dr. Porter said "abort" is an unfortunate and misleading word. We can decrease the intensity and cut shorter the duration of an attack with such remedy.

It cannot be abortion in any germ disease.

Dr. J. B. Herrick said in an experience with over one thousand cases of typhoid fever, he is inclined to think that there is no specific for the condition. For the febrile condition he does not consider anything equal to the cold bath. Even Woodbridge's treatment is an expectant one.

Dr. Woodbridge, in closing, made reference to former discussions and papers by himself and others. Even if we could exclude the diagnosis of genuine typhoid in these cases, what better treatment can we find for the condition? When, however, the rose spots appear along with the usual symptoms, we must admit it is typhoid fever, and these cases can all be aborted in a few days.

Treatment of Pulmonary Consumption in Hospitals.—Dr. E. L. Shurly, of Detroit, presented the paper. For many reasons the treatment in general hospitals is not practicable. Other patients and dangers of contagion, whether real or imaginary, are important factors. Home sickness and poverty are also against it. Foreign hospitals for tuberculosis are successful, but the conditions are different in this country. The Harper Hospital of Detroit has been the nearest of success of any American institution. Americans are too restless and have not patience enough to test the

system. The hospital must not only be thoroughly equipped, but located in an equable climate.

The Direct Cause of Tuberculosis.—Dr. Gustav Fütterer, of Chicago, presented this paper. The history of the disease was given, along with some interesting remarks regarding Koch's work and demonstration of the tubercle-bacillus. The means and ways of infection were detailed, and the probability of danger to the healthy individual fully demonstrated inhalation, food, drink, direct injection of bacillus into wound, and heredity being the chief means of infection. What can be done to arrest its spread? 1, Early diagnosis; 2, disinfection by every possible means; 3, care by the patient; 4, care by friends and attendants; 5, personal cleanliness—bathing; 6, avoid kissing at all times; 7, teeth and mouth especially clean; 8, sleep alone; 9, should not attend public or private gatherings; 10, be careful of expectoration; 11, go to special hospitals for treatment.

Scrofulosis and chlorosis were considered in their relation to tuberculosis, and treatment and diet for each dwelt upon at length.

The curability of consumption depends greatly on whether the patient comes early for treatment. The author's treatment is the oil of cloves. 1. A No. 1 gelatine capsule is filled with pure oil of cloves and taken with a glass of milk every two hours from 8 A.M. to 10 P.M. 2. If the oil is tolerated, one capsule should be given every hour. 3. Oil of cloves and cold-pressed olive oil are mixed in equal parts and injected hypodermically, a syringeful once or twice daily. This is continued for four weeks, stopped for two weeks, and then resumed.

The Treatment of Acute Inflammations of the Middle Ear and Mastoid Process.—This paper was read by Dr. E. B. Dench, of New York. For convenience, the author anatomically divided the middle ear into two parts by a line drawn through the styloid process. Inflammations in the middle ear produce the ordinary results of the same process elsewhere within a cavity lined by a mucus-producing membrane, but because of transfusion the tissue necrosis is not so extensive; yet there is enough retained to cause an outward bulging of the tympanic membrane. If seen early, free blood-letting should be practised and a single dose of an opiate given. Do not give but one dose of the opiate under any circumstances. Also apply dry heat locally. Do not use wet heat. If not seen until later, free opening is the only thing to be advised. The technique of the operation was minutely and carefully described. The more acute and severe the case, the more prompt should be the measures for relief. An incision should be made often, even when it is known the cavity contains no fluid. The incision does not end the danger; the entire cavity must be thoroughly washed out and made antiseptic by irrigation.

Sequelæ of la Grippe.—This paper was read by Dr. F. C. Heath, of Indianapolis. Several cases of eye results were given, and the more common condition of ear complications noticed, with treatment considered.

In the discussion, Dr. Straight thought the stomach was the most frequently affected of all organs. Dr. North said quinine given for la grippe had done more damage than any other one thing. Dr. Wheelock saw two distinct kinds of reaction following in ear cases with periostitis or middle-ear abscess.

Artificial Ripening of Cataract.—Dr. J. M. Ball, of St. Louis, read a paper with this title. A complete history of the operations was given and the various methods were explained. Before doing any of them the surgeon should be sure the zonula is intact, the tension normal, and the pupil dilatable. Division of the anterior capsule in these cases is always more or less dangerous, and may be serious. Bettman's operation or direct massage or trituration is, of all, the most desirable. It is the least dangerous, most certain, and speedy. It has stood the vital test of experience and is worthy of confidence. If prolapse of the iris occurs, snip it off at once, contrary to most authority, but he had found it satisfactory and beyond expectations.

Complications in Cataract. Arising from Diabetes, Albuminuria, Etc., was a paper by Dr. J. O. Stillson, of Indianapolis. The diabetic cataract is as yet a puzzle. A serous retinitis is often a symptom of Bright's disease. Albuminuria is a frequent complement of cataract. It is not only desirable but necessary to treat these conditions if they exist before operating for the senile cataract.

Rheumatism and Gout in its Relation to the Eye was the title of a paper by Dr. K. K. Wheelock, of Fort Wayne, Ind. The paper was a thoroughly practical one and presented this somewhat old but nevertheless important subject in an interesting manner and elicited a warm discussion.

Bio-chemistry in its Relation to Nervous Diseases.—Dr. G. W. McCaskey, of Fort Wayne, Ind., followed with a contribution on this subject. In this paper the somewhat peculiar and certainly novel attempt was made to establish the general theory of the causation of nervous diseases by chemical poisons circulating in the blood and acting by a process of selective affinity upon different parts of the nervous system. The author referred to these poisons under the following groups, the classification being entirely tentative, and based upon their source of origin instead of their ultimate chemical analysis or physiological action: 1, Bacteriological products—ptomaines; 2, products of perverted tissue metabolism; 3, defective elimination of excretion; 4, perverted secretion of glandular organs; 5, products of imperfect digestion; 6, chemical compounds probably present in independent blood states and of unknown origin. Many conditions heretofore unknown as to their etiology will be found to be due to one of the above conditions existing in the system.

How shall we Rear our Babies?—One of the most practical papers of the section was that read by Dr. J. H. Taylor, of Indianapolis. The suggestions and directions were for both physician and mother, and put in so pointed a manner that the paper ought to have a wide circulation.

Diseases of the Mouth, Nose, and Throat as Etiological Factors in Chronic Glandular Gastritis, with Bacteriologic Studies of the Pharyngeal Vault.—This was the title of a paper by Dr. Fenton B. Turck, of Chicago. Bacteriologic study has developed the fact that upon the mucous membrane of the mouth, nose, and pharynx groups of micro-organisms may form, which may also be found growing on the mucous membrane of the stomach, and certain germs that are found in the inflamed mouth may also be found growing on the walls of the stomach in gastritis. Under normal conditions the mucous membrane of the stomach does not favor colonization upon its walls; but let some etiologic factor come into play and micro-organisms will develop. The mouth, nose, and throat, when in a diseased state, become incubators ready to infect when the conditions of the stomach permit the development of growing micro-organisms upon its walls. The author then referred to the bacteriologic studies of Miller, Wurtz, and Lindet. Micro-organisms of the mouth are carried by the food after mastication into the stomach; many of them are again recognized in the stomach, and in cases of gastritis are found in colonies growing upon the mucous walls. The author in his clinical and experimental work has presented similar groups of micro-organisms taken from the gums and cavities in the teeth, as well as from the material removed by the gyromele (revolving sound) from the walls of the stomach. In cultures upon the prepared mucous membrane of the pig he has been able to cultivate some of the micro-organisms and find the same developing in the stomach that are found in the mouth. But in the control animal he has not yet found micro-organisms growing in colonies in the stomach.

After reporting several cases, Dr. Turck concluded hat clinical observation indicates a marked relation etween diseases of the mouth and post-nasal cavity nd chronic inflammation in the stomach and intestines ; hat the invasion of the stomach from the infected outh and pharynx is supported by the fact that many f the non-pathogenic micro-organisms present the dentical biological and physical forms in cases of gas-ritis the same as those found in diseases of the mouth nd post-nasal cavities of the same patients.

Dr. Turck exhibited a chart showing the predominat-ng micro-organisms found in eight cases that were tudied bacteriologically.

In the discussion, Dr. Larrabee, of Louisville, said hat the germ theory had been superseded by germ acts as presented.

Dr. Frank Billings, of Chicago, complimented Dr. Turck on his excellent clinical and experimental work, aying that the doctor stands at the head of his pro-ession in the work he has accomplished. He had hown that when there is a lowered vitality of the mu-ous membrane of the stomach by errors of diet that a oil is produced favorable for the development of mi-ro-organisms.

Experiences with Paquin's Antitubercle Serum in the Treatment of Laryngeal Tuberculosis.—Dr. H. W. Loeb, of St. Louis, read a paper in which he gave the istory of nine cases of this disease, seven of which had een treated with the serum. The patients all improved reatly. One case particularly lost all dysphagia, pain n the larynx, cough, and night sweats. Other patients owed a much greater improvement than under any ther plan of treatment yet tried. The doctor quoted ie confirmatory evidence of Maregliano, of Genoa, ole, Semon, Wiggins, and Paquin. He will continue is investigations and present further conclusions at a ter date.

In the discussion, Dr. Paul Paquin, of St. Louis xplained in detail the treatment which he has pro-uced. He said it was just in its beginning. It will ave to be improved as we go along, and it will take ears to do so. The best results have been obtained n the acute forms of the disease, and not in the chronic. he law underlying serum therapy is a natural one. It trying to fight bacteria by using nature's remedy. le had had failures with serum, but he could mention orty or more cases of recovery. He thought that in ome cases it would require other treatment except rum. He had not had good results inside of two or ree months, and it frequently required five or six onths, or even longer. He had made over ten thou-nd injections with serum in tubercular cases, but did ot recall one which was attended with fatal results. e counselled study of the climate, as well as the pa-ent, before sending a patient away. Tuberculous atients could not live in Colorado or New Mexico. hey will die quicker there than anywhere.

Yeast Nuclein and its Therapeutic Uses.—Dr. Victor . Vaughan, of Ann Arbor, Mich., presented this paper. hysiologically nucleins form the chief chemical con-ituents of the living parts of cells ; that constituent of e cell, by virtue of which this histologic unit grows, evelops and reproduces. The nuclein of various lls differs, and is limited only by the variety of cells. hemically the nucleins contain a large amount of phos-horus. Some are combined with albumin, forming the -called nucleo-albumin. The nuclein molecule has a markable power of recuperation after partial decom-osition. Some nucleins have germicidal properties. xperiments were made with animals apparently proving at previous treatment by the nuclein gave immunity to e pneumococcus. Some thirty experiments were de-iled and results given which seemed quite promising.

Diagnosis of Hysteria was the title of a paper by Dr. ugh T. Patrick, of Chicago. The writer dwelt par-cularly upon the peculiarities of hysterical anæsthesia, yperæsthesia, and paralysis. The principal peculiar-ities of the first are its distribution in the form of a glove, sleeve, or stocking, with sharply cut border, and in dis-seminated and irregular patches. Dr. Patrick called attention to a distinguishing trait not yet described, namely, almost instantaneous shifting of the line of de-marcation between the anæsthetic and normal areas. This peculiar feature applies equally well to hyperæs-thesia. Among the hyperæsthesias was described hys-terical joint disease, and hysterical angina pectoris, with the differential points of diagnosis between these affec-tions and organic disease. The peculiarities of the hysterical gait were described at some length, and their relation shown to the affection described by Blocq, and called by him astasia abasia. The writer protested against this affection being considered a nosological en-tity, as it is simply an exaggeration of a common feature in hysterical paralysis. The peculiarities which distin-guish a hysterical from an organic paralysis of the upper extremity were also described, and hysterical affections of the special senses were briefly alluded to.

Hæmorrhoids—Prolapse Rectum—A New Operation.—Dr. B. M. Ricketts, of Cincinnati, read the paper. The object of this paper was to present means more simple than had heretofore been offered for the radical cure of a prolapsed rectum and the obliteration of hæmorrhoids. After widely dilating the sphincter with the fingers under surgical anæsthesia, a large semi-circular needle is passed subcutaneously from the mu-co-cutaneous line to the upper border of the pile-bearing area, and then returned to make its exit at the point of entrance. The needle is then removed, and the silk ligature made tight about the venus plexus, and the ends left hanging out. These ligatures may be from one-half to an inch apart as the case may require. It is not necessary to tie all the varices in this way, as the atrophic changes will necessarily obliterate the re-maining ones. No tissue is sacrificed : the mucous membrane remains intact ; there is no hemorrhage, no infection, no pain of consequence, and the loss of time is practically *nil*. The sutures are allowed to come away of their own accord. The operations made in this way for this condition have resulted in an ab-solute cure, and the patients have experienced but little pain during the life of the ligature.

Prolapsed rectum is treated in the same manner, ex-cept a great number of ligatures are required. If they are properly and evenly adjusted, the atrophy of the tissues is symmetrical, and the pathological condition is relieved without stenosis.

Daniel Drake, or Then and Now.—Dr. William Pepper, of Philadelphia, by request, delivered the ad-dress on medicine. He selected for his subject "Dan-iel Drake, or Then and Now." Daniel Drake died in Cincinnati in 1852. He was universally recognized as the leading medical man of the West. He graduated at the University of Pennsylvania in 1816, the excep-tional honor of a special commencement held for this purpose being granted to him. He had already prac-tised medicine for twelve years without a diploma, and had won a high reputation by his scientific and literary work. Dr. Drake received no fewer than thirteen sep-arate calls to medical professorships, and actually held at different times nine chairs in five separate institu-tions, in Cincinnati, Lexington, Louisville, and the Jefferson Medical College in Philadelphia. Dr. Gross, who was a colleague in two institutions, pronounced him the most forceful and eloquent teacher he had ever known.

The Deflected Septum and its Repair.—This paper was read by Dr. J. Homer Coulter, of Chicago. The author first dwelt upon the etiology of the condi-tion. In stenosis of any degree there is created, in each inspiration, within the cavity, a more or less com-plete vacuum. Thus the atmospheric pressure is to that degree increased and is a constant force of no in-considerable gravity. He holds further that such a force would be more efficient in producing structural

changes in the cartilaginous septum than would a more violent force suddenly applied, because the natural cartilaginous resiliency would more easily recover and throw off the effect of the latter.

The author then gave the points in the operation, because in the observance of those lies the success of the operator. Where the deviation is well anterior, or involving merely the alæ, it is very much simplified because of convenience in operating and after-treatment as well. Until recent years but little attention was paid to the preservation of the mucous membrane when operating on a deflected septum. A new form of punch was suggested for removing the cartilage and leaving the membrane intact.

A Case of Comminuted Fracture of the Ilium with Specimen and Photographs, by Dr. W. F. Breakey, of Ann Arbor, Mich. No reports show such an extensive fracture of the ilium as this case. It was literally shattered into pieces. The patient fell ten feet on a pile of stones, producing this fracture and also a Colles's fracture with dislocation of ulna. The patient never rallied from the shock of the accident.

The Treatment of Cancer, by Dr. Hal C. Wyman, of Detroit. The cure of cancer is rare, and unless the treatment is begun early, the disease terminates in death. In the treatment of cancer there is still an open field. The cure by early removal, while the disease is local, is urged and practised by all who have opportunity. But the opportunity will not occur with sufficient frequency to stamp out the disease until the people are educated as to the facts.

Laryngitis from a Rhinological Stand-point.—Dr. Lewis C. Cline, of Indianapolis, read a paper on this subject. The author adheres to Bosworth's classification of laryngitis, and applies the word *itis* only to inflammations of a purely catarrhal character, which excludes at once, syphilis, tuberculosis, and other constitutional diseases, as they are more properly called syphilis or tuberculosis of the larynx. The cases that are least amenable to treatment are the atrophic, but much can be done to comfort and palliate these cases by attention to dress, stimulant and lubricant applications. For stimulating and astringing he finds nothing equal to nitrate of silver, from 10 to 40 grains to the ounce, according to indications. For overwork cases the first law is rest, with occasional mild, stimulating applications with an atomizer. The great majority of cases that had come under his observation had had atrophic or hypertrophic rhinitis to a greater or less degree. Spurs and deflected septum are often associated with these conditions. The lesions most frequently observed are hypertrophies of the posterior ends of the inferior turbinate body, and a thickened, lumpy condition of the posterior end of the septum. The drill, saw, snare, and galvano-cautery are aids in removing these conditions in the more aggravated forms, while the applications of silver and various astringents with sprays had served the author in the mild form.

The Therapeutics of Oleo-creosote and Creosote Carbonate.—Dr. J. A. Wessinger, of Ann Arbor, Mich., contributed a paper on this subject. He summed up his experience with these remedies in the following conclusions: 1. The dosage is practically unlimited as far as toxicity is concerned, but it is preferable to begin with a small dosage, two to three drops after eating, and increase until the desired result is obtained. 2. To be of value in tuberculosis a clinical diagnosis must be made early. 3. While these agents are distinctly germicidal, they also serve as tissue-builders. 4. Creosote carbonate and oleate have the power of increasing the number of red blood-corpuscles, and they also increase the percentage of hæmoglobin in the blood.

The Bicycle from a Medical Stand-point.—Dr. I. N. Love, of St. Louis, read a paper with this title. Bicyclists should understand the importance of going reasonably slow. The wheel brings into play all the muscles, and the maintaining of equipoise has beneficial results. The matter of position is important. The rider should maintain an erect posture and not assume an unsightly stoop in imitation of the hoop-snake, which takes its tail in its mouth and sails through the country. A study of the question of the wheel for women had resulted in an opinion favorable to its moderate use in cases of acute diseases. Specialists had agreed to this. Numerous cases of long-standing pelvic diseases had been benefited by a judicious use of the bicycle. Women maintain a better position than men. An hour's wheeling three times a day is ample. The costume is important from the stand-points of health and art. He objected most emphatically to bloomers, which lessened the respect of mankind for womanhood and blemished the landscape. Leggins and accordion-plaited skirts were about the thing. Corsets should be put aside. Skirt and shirt waist were favored, and even the sweater was approved.

The discussion was opened by Dr. C. B. Parker, of Cleveland, and continued by Dr. W. M. Wishard, of Indianapolis; Dr. Sterne, of Indianapolis; and Dr. Walker, of Evansville, Indiana. They all advocated and advised a moderate use of the wheel for both men and women.

A paper was read by Dr. T. O. Summers, of St. Louis, entitled "The Physiological Aspects of Leucocytosis," and one by Dr. A. Goldspohn, of Chicago, on "The Proper Indications for Repair of Pathological Lacerations of the Cervix Uteri, and for the Relief of Pathological Ante-flexions and the Proper Operations to Meet them."

Election of Officers.—The Nominating Committee reported as follows: *President*, Dr. H. O. Walker, of Detroit; *First Vice-President*, Dr. B. M. Ricketts, of Cincinnati; *Second Vice-President*, Dr. F. C. Woodburn, of Indianapolis; *Secretary*, Dr. H. W. Loeb, of St. Louis; *Treasurer*, Dr. H. N. Moyer, of Chicago; *Judicial Council*, Drs. W. N. Wishard, T. E. Holland and A. P. Buchman. The report of the committee was adopted and the nominees declared elected.

The Nominating Committee also submitted the following resolutions:

Resolved, That it is the sense of this Committee that the best interests of the Association will be subserved by the appointment of a permanent Executive Committee, composed of the titulary officers of the Association and the ex-Presidents, and that this Committee shall conduct all the business of the Association: be it further

Resolved, That we recommend the creation of the office of Assistant Secretary, to be appointed by the Chairman of the Committee of Arrangements, from the place in which the meeting is held.

On motion, the Association adjourned, to meet in St. Paul, Minn., on the third Tuesday of October, 1896. Dr. C. A. Wheaton, of St. Paul, was selected Chairman of the Committee of Arrangements.

A Woman Coroner.—The Omaha *World-Herald* says that the city physician and coroner of Pender, Neb., is a woman, who was elected unanimously last autumn after she had been but six months practising in the town.

Inherited Age.—Dr. B. W. Richardson gives a series of observations on the duration of life of the offspring as compared with that of the parents. He considers that if the ages of the two parents and of the four grandparents be added together and divided by six, the age of the case in point will be told, with an average variation of not more than two. If the ages of the parents are high the offspring tends to improve on them; if low (say an average of forty or lower), the life of the offspring will probably be still shorter.—*Dublin Journal of Medical Science.*

Clinical Department.

MATERNAL IMPRESSION.

By F. W. MALONEY, M.D.,

ROCHESTER, N. Y.

Mrs. F—— came to my office in the early part of November, 1894, complaining of a whitlow about her left thumb-nail. She was about six months pregnant. The pain was severe, and I made a small incision to let out the pus and applied antiseptic dressings.

On the 25th of last month I was called to attend her in confinement, and delivered her of a male child. While examining the infant, as it was being washed by the nurse, I found that the left thumb was bifid, that is, there was a supernumerary thumb fully formed with nail, apparently grown out of the primary articulation of the first phalanx. The double thumb gives a Y-shaped appearance. The mother is of an extremely nervous character, and I have no doubt that this is a clear case of maternal impression.

A CASE OF PILONIDAL FISTULA.

By HARLAN M. PAGE, M.D.,

HIRAM, O.

PROFESSOR OF MEDICAL SCIENCE AND BIOLOGY IN HIRAM COLLEGE.

Mr. H. V——, aged twenty-three, stalwart and strong, with negative family history, sought relief at my hands for a discharge from the anal region, which he had first noticed as staining his linen some four weeks prior to this consultation, which was February 10, 1894. On inspection I found two small apertures—the lower one at about the sacro coccygial articulation, and the other about an inch above. On pressure I was able to bring to light some considerable pus from both openings, which especially attracted my attention in that it was devoid of odor. I next demonstrated the existing channel between the two openings by the injection of peroxide of hydrogen, which procedure is to my mind much more satisfactory than the use of the probe, which so often is made to demonstrate fistulæ and sinuses which exist only in the mind of the operator. Failure to pass either peroxide or probe into rectum committed me to the diagnosis of incomplete external fistula. As the patient had never suffered from constipation and was unable to recall the receipt of any injuries in this region, I finally concluded that much riding upon a hard and often damp seat of a meat wagon must stand responsible, at least tentatively. The patient fearing the knife, I began the use of nitrate of silver applications, following thorough cleansing by peroxide of hydrogen; and after pursuing this course for some ten days, I was slightly surprised to find at one of the openings, in the débris which the peroxide of hydrogen had brought out, a dozen or fifteen hairs about three-fourths of an inch in length and arranged in the form of a little curl. I continued my treatment for another ten days, with no improvement; however, the daily appearance of two or three hairs was slowly stimulating my mind to a new diagnosis. I finally recalled an obscure sentence in Ashhurst's surgery, which I quote: "It must be remembered that every sinus in the neighborhood of the anus is not necessarily a fistula in ano; it may, for instance, be connected with caries or necrosis of the tuber ischii; may depend upon the pressure of a tuft of hair, as in curious cases observed by J. M. Warren and other surgeons, including Lamadrid Gaston, Wyeth, and myself; or may communicate with an abscess arising within the pelvis or proceeding from the hip-joint." Having verified this memory, I looked in vain through my library and journals for another hint on this subject. At the next visit I made a free incision connecting the two openings, and was rewarded by bringing to the surface a tuft of perhaps a hundred hairs. Curettement and the application of pure carbolic acid secured an early termination to this rather unusual case, which I suppose must be explained as resulting from the invagination of epithelial cells during the embryonic development of the individual. How much the irritation of the hard, damp wagon-seat had to do with bringing the trouble to light we can only conjecture.

DERMOID CYSTS AND PREGNANCY.

By JOHN A. PRINCE, M.D.,

SPRINGFIELD, ILL.

Mrs. H. D. E——, aged twenty-six. About four months ago she first noticed a growth in the right side of the abdomen, quite low down, which has been steadily enlarging and occasioning considerable pain. Menstruation ceased about a month before she noticed the tumor. She says her mother told her that when she was a child there was a tumor present, which as she grew older disappeared. An examination revealed the uterus, about five months pregnant, high up, with the os close up against the pubic bone, and the fundus to the right. This composed the tumor noticed by patient. Occupying the pelvis was a cystic tumor about the size of a cocoa-nut.

An early operation was advised, and done a few days later, April 6, 1894. Considerable difficulty was experienced in removing the growth, necessitating the removal from the abdomen of the fundus uteri, in replacing which a good deal of manipulation was necessary. This was finally accomplished by passing a tube down alongside of the uterus into the pelvis, permitting the air to escape; then the uterus slipped in easily.

The tumor contained an oily fluid of the consistence of melted butter, and a large mass of hair. On April 12th, six days later, there were strong signs of labor, but they subsided under appropriate treatment. There was a normal labor at term, and mother and child did well.

SUCCESSFUL USE OF ANTITOXIN FOR DIPHTHERIA IN COUNTRY PRACTICE.

By DANIEL B. SPRECHER, M.D.,

SYKESVILLE, MD.

On April 29th the grandmother of a family, in which there were five children ranging in age from twenty-three months to eleven years, died, was placed on ice in an ice-box, which was found to have a broken or cracked zinc lining running two-thirds the length of one side, the wood under the fissure being in a soggy state. With the melting of the ice there began dripping from this side a stringy, slimy, mucus-looking substance, together with an odor so horrible and sickening as to require the removal of the box and the adoption of other methods of preservation of the body. Upon the return of the funeral party the granddaughter, eleven years of age, was directed to wash and wipe up the stains on the floor made by drippings from the ice-box. This she did thoroughly, and on Saturday, four days later, complained of sore throat, fever, and general malaise. The next morning it was ascertained she was suffering from diphtheria. Membranous deposits over tonsils, pharyngitis, lymphatic tumefaction, with characteristic nasal conditions, appearing in a few days.

Notwithstanding isolation was prompt and apparently thoroughly maintained, the youngest child fell a victim to the disease ten days later. On the third day of its illness croup complicated the case, but under

treatment apparent relief was obtained, till the following evening, when it (croup) reappeared in such a serious form that I called Dr. L——, a fellow practitioner. He advised tracheotomy. To this the parents objected. I then called attention to antitoxin and obtained consent to its use. The next morning 10 c.c. of Berling's antitoxin was injected in the region of the left hip. Two hours later the struggling for breath, which was painful to witness during the night, together with cyanosis, coldness of extremities and anxious restless movements of child, grew calm, easy, and sleep followed, as did also glowing surface and slightly accelerated temperature, rising from a subnormal of 98⅘ to 99° F. The sleep continued for four hours, disturbed more or less from coughing, after which the child awakened refreshed, asked for beer, and drank heartily. Five cubic centimetres were injected the next day in opposite hip. On inspection of membranous patches as far as could be seen in the throat they seemed to dissolve away to thinness. The 15 c.c., together with a spray of peroxide of hydrogen, twenty-two per cent., and lime-water inhalations secured constant improvement, ending in recovery within a few days.

Interesting facts: 1. Inspection of the premises failed to reveal any cause for diphtheria; absolute absence of diphtheria in neighborhood; no history of diphtheria in any person or family attending funeral. Suggest cause to have been a contaminated defective ice-box. 2. The prompt and wonderfully efficient action of antitoxin, even after the disease has invaded the laryngeal passages.

MORPHINE POISONING.

By A. C. McDONALD, M.D.,

WARSAW, IND.

At 6.30 A.M., August 22d, I was called to a young man, aged eighteen, who had taken twenty grains of morphine with suicidal intent. He was in a condition of profound stupor, almost comatose, with respirations four a minute; pulse 110, and fairly strong; pupils like pinholes. It was thought that he had taken the drug at bedtime, and consequently did not resort to the stomach-pump at once.

Atropia, $\frac{1}{75}$ grain was injected hypodermically, and permanganate of potassium, 10 grains, was given both internally and hypodermically. In the course of an hour, at 7.30, his condition was apparently not improved. I now injected strich., sulp. $\frac{1}{10}$ grain, and half an hour later his respiration reached five or six a minute. At this time he aroused himself sufficiently to tell that he had taken the poison at five o'clock. Considering the quantity was large I sent for Dr. White to help me use the stomach-pump. We thoroughly washed out the stomach. He still continued in a deep stupor, from which we could not arouse him save with electricity; when aroused his respirations generally increased about one a minute.

His respiration from this on was sustained by strych. sulp., $\frac{1}{10}$ grain every hour or two, according to condition of respiration. Of this he had taken about ¾ of a grain in all in the twenty-four hours without any symptoms of strychnine poisoning. At 6.30 P.M. patient seemed sufficiently improved that I thought it safe to leave him with nurse and his father, who was a physician. They walked him about considerable after I left. I was soon called back in haste, and found him completely comatose, with pulse 160, scarcely perceptible; respiration two a minute. I now injected spirit of ammon. arom. and tincture of digitalis every fifteen minutes. Condition appeared almost hopeless at this time. Ammon. and digitalis were repeated every fifteen minutes, with occasional trial of artificial respiration and strychnine. Patient soon improved, with respiration ten or twelve. Pulse, 150.

Patient was now allowed to sleep while respiration kept up, and heart sustained with ammon. and strychnine during the night. At 6 next morning patient was conscious and recovery soon followed.

The above case seems of interest from three points of view. In the first place, the apparent inefficiency of the potassium permanganate in spite of the reported success by many physicians, particularly Dr. Moor. Secondly, the greater efficiency of strychnine as a respiratory stimulant compared with atropia. I believe the former should be used more in these cases and in larger quantities. I am sure I could have used more with perfect safety. Thirdly, the great harm that can be done by exercising an exhausted patient. I could scarcely persuade his father that exercise simply helped, in the absence of other sources, to keep patient awake that he might voluntarily help in maintaining an exhausted respiratory centre.

The severe exercise baffled an exhausted circulation, and a patient which was apparently doing well might easily have been lost by rash and injudicious treatment.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

THE BATTLE OF THE CLUBS AT CORK—THE JUDICIAL PERSECUTION OF DR. ANDERSON—THE LUNACY REPORT—HEALTH OF LONDON.

LONDON, September 7, 1895.

The question of club attendance at Cork is not yet settled. A conference was lately held, at the instance of the Mayor, between representatives of the clubs and the profession. The rules agreed to by the doctors were carefully considered seriatim, and some modifications were accepted to meet the views of the clubs. But these concessions did not satisfy the delegates, who wanted the doctors to take into association and meet in consultation the three practitioners who had been imported to carry on the contest. This proposal was repudiated by the representative doctors, who declared that under no circumstances could they hold professional intercourse with these persons. As the delegates from the clubs stood firm on this point, the conference proved a failure. The three young men who went to Cork to supersede those who were fighting the battle of the profession, knew very well what they were doing, and can hardly have expected that they would be received as professional brethren after they had behaved in this way. It is to men of this stamp that the profession owes many of its troubles, and they must take the consequences of their disloyalty. If they have no regard to professional honor, they would do well to follow some calling in which the conduct and feelings of a gentleman are not expected. It is, alas, true that in the higher walks of the profession similar conduct has been known—witness the Throat Hospital case in London—but that is no excuse, and the profession in London ought not to show itself less alive to its honor than in Cork. It would be well if the example of Cork should be widely imitated.

The case of Mr. R. B. Anderson excites considerable interest and deserves all sympathy. He is undoubtedly the victim of a monstrous injustice. His wrongs were so manifest in Tobago that he was sent by public subscription to England to appeal to English courts against the partiality and malice of the local judges. In the Queen's Bench the facts proved could not but excite astonishment. A Royal Commission was issued to inquire into the administration of justice in Tobago. The result was that one of the judges was removed from office, the other was interdicted pending the trial of the charges against him, but he has in the meantime died. The jury found a verdict amounting to malice in the

exercise of their functions by the judges, and awarded damages. But the judge entered judgment in their favor on the ground that no action lies against a judge for an act done in his judicial capacity, and this ruling has been confirmed by the Court of Appeal. It is therefore clear that Dr. Anderson is the victim of a persecution which disgraces the judicial bench, and for which the law provides no redress. The boast of lawyers that "every wrong has a remedy at law," is therefore shown to be a fiction, and the immaculate purity of English judges must be held with reserve until the Bench find some method of upholding the right, punishing any offending member, and compensating the victim of such persecution. Dr. Anderson has maintained his honor against all the difficulties thrown in his way by judicial persecutions, but at what a cost! practically ruin. The prosecuting judicial criminals ought to be made to compensate him and to retire for a season to the seclusion of one of her Majesty's prisons. Such an example would do much to restore confidence in British justice and the impartiality of the English Bench. If no way can be found of making such an example, Parliament should interfere. No doubt the ministry would be willing to promote an act of simple justice if the Bench would unanimously recommend some such method of upholding its honor.

The Forty-fifth Report of the Commissioners in Lunacy shows an increase in the number of patients on January 1, 1895, over that of 1894. There has in fact been a continual increase for many years, but it does not follow that lunacy is absolutely increasing in the country; more persons are now received in the asylums on account of the mental decay of old age. Then there is the constant accumulation of chronic cases and the diminution in the death-rate. Taking these and other circumstances into account, it is probable that the nation does not contain a larger number of lunatics of late years, but the subject has certainly received more attention than formerly.

The Registrar-General's returns for the week show a slight decrease in the deaths from small-pox and scarlet fever, but there is an increase in the mortality of whooping-cough and diphtheria. Still the deaths from all causes were ninety-eight less than the decennial average. Our annual death-rate per 1,000 has fallen from 17 to 15.9, and for a month past the average has only been 17.3, which is 1.1 below the mean rate of the last ten years, so that London cannot be called unhealthy.

INTERNATIONAL LANGUAGE.

To the Editor of the Medical Record.

Sir: It is impossible to answer in the form of a short letter the remarks of Dr. Ferd. C. Valentine on the question of an international language, which appeared in the Medical Record issue for August 24, 1895. While I intend at some future time to enter quite thoroughly on the choice of Dr. Valentine to have the Spanish in preference of the Greek language, and to give full credit to some of his observations which are quite correct, I wish to call attention to-day to a word in favor of Greek, said in the year 1824, that is before Greece had become a nation again, by one of the noblest Philhellenes, the great philologist, Claude Charles Fauriel:

"The modern Greek is a language remarkable in every respect. Having a foundation as homogeneous as but even richer than the German, being as clear as the French, smoother than the Italian, and more harmonious than the Spanish, there is nothing wanting to consider it from this time on as the most beautiful language of Europe. She is without the shadow of a doubt idiom, at perfect. If she can be compared with any of which she with the one from which she originates, and a new phase. Granted there were some inferiority, it will be only temporary. Let the Greeks become a nation; let this nation have great writers who understand well that the glory and the prosperity of their country are things of the future, not only of the past; that these things are before them, not only behind them; that they are to come in the ordinary run, and not by the vain attempt of a return to the past; and the modern Greek will soon be a language which, without resembling more the ancient as it does now, will have no cause to envy it."

A. Rose, M.D.

336 East Fifteenth Street.

New Instruments.

A KNIFE-NEEDLE FOR DISCISSION OF THE CAPSULE AFTER CATARACT EXTRACTION.

By JOHN E. WEEKS, M.D.,

NEW YORK.

The instrument described here was devised for the purpose of discission of the lens capsule (not thickened by inflammatory reaction), which remains after the extraction of cataract, with the least possible traction on that membrane. The endeavor has been made to produce a knife in the use of which the cutting edge may be made to present at right angles to the plane of the capsule at all times during its passage through the membrane. For this purpose a curved knife-needle has been devised so made that the incision through the

cornea is perfectly filled by the shank after the blade has entered the anterior chamber, preventing loss of the aqueous tumor. In order to have knives suitable for all cases they are made in sets of three, each set containing a knife have a cutting edge of 3.5 mm., 4 mm., and 5 mm. The blade is about two-thirds of a millimetre wide in its widest part. The curve of the blade, which begins near its heel, is such that the extreme point of the blade is found to be about two millimetres distant from a line projecting along the axis of the shaft. The concave edge, the point, and also the convex edge to a distance of 1 mm. up from the point, are made as sharp as possible.

The passage of the knife through the cornea is not so easily effected as with the straight knife-needle, since the curve of the needle must be followed in order to avoid making an incision too large to be filled by the shank. The needle is entered on the flat, penetrating the cornea at a point on the horizontal meridian midway between the centre and the temporal margin of the cornea. The cutting edge is turned toward the capsule after the blade has passed fully into the anterior chamber; the knife is withdrawn in the reverse order.

The curved knife-needle appears to possess the following advantages over the straight knife-needle: 1. The incision through the capsule can be made with more ease and certainty. 2. The traction on the ciliary processes, through the medium of the capsule, is less. 3. It can be manipulated more easily when the blade is in the anterior chamber. 4. The point of the knife need not enter so deeply into the vitreous humor.

The knife is made by E. B. Meyrowitz, New York.

American Students in France are admitted to the higher courses of instruction in the medical and other faculties of the universities, but cannot obtain degrees unless they have already a French bachelor's degree. A movement is under way to admit to the higher degrees graduates of American universities of good standing.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending September 21, 1895.

	Cases.	Deaths.
Tuberculosis	80	120
Typhoid fever	48	17
Scarlet fever	19	1
Cerebro-spinal meningitis	3	3
Measles	38	5
Diphtheria	101	12

Pseudo-meningitis. — Dr. Krannhals reports seven cases in which the symptoms were almost exclusively nervous, and in which the diagnosis of meningitis was made, although some of the more characteristic symptoms were wanting. One case ended in recovery; the termination of another could not be determined; five died. The findings at the post-mortem examination did not confirm the diagnoses, there being no exudate, no inflammatory turbidity, nothing but hyperæmia and œdema of the pia, and a varying number of hemorrhages in the same membrane. The microscopical examination of two cases confirmed the pre-eminent hemorrhagic character of the affection, and the absence of any real inflammatory changes, if one does not regard as such the œdema of the pia, which in reality had the character of an œdema due to congestion rather than inflammation. The brain itself showed no inflammatory changes; on the contrary, here and there, in the superficial layers of the cortex, there was a retrograde metamorphosis, a beginning necrosis due to a disturbance of the circulation brought about by the numerous hemorrhages in the pia. Bacteriological examination of the meningeal serum of three cases proved negative. Krannhals seeks to explain an intimate relationship between influenza and these cases of "pseudo-meningitis," occurring as they did during the spring of 1890, following the influenza epidemic. He believes that the symptoms of the cases of "pseudo-meningitis," due to some infectious process, and of acute meningitis in general, depend especially upon the action upon the central nervous system of certain toxines, and secondarily upon the anatomical lesions present.—*University Medical Magazine.*

Texas Fever.—It has long since been observed that this disease is of an entirely infectious character; that it is not communicated from cattle to cattle by direct contact, but that cattle bearing the infection, when allowed to graze on uncontaminated grounds, will sow the infection, being all the time in apparent health themselves, in which condition they will remain. When susceptible cattle are allowed to graze with such cattle, or have been allowed to occupy pastures that have been occupied by such cattle, they will contract the disease and die. This curious fact that cattle can spread fatal infection on susceptible grounds while they are in apparent health and remain so, is explained by numerous observers. The cattle that are raised from birth on the range lands acquire an immunity against the disease, by gradual inoculation as it were, and if they are ever affected, it occurs during their early life, assumes a light form, from which they recover. At an early date in the investigation of this disease and its manner of communication, it was observed that the cattle-tick, that abounds on all the range lands of the infected area, was nearly always present in large numbers where outbreaks occurred, and was in some way connected with the communication of the disease. Experiments made by Dr. Theobald Smith, Pathologist for the Bureau of Animal Industry, revealed the connection the cattle-ticks have with the communication of the poison that produces the disease. When fully matured the ticks drop from the cattle to the ground, lay their eggs and perish, thus ending their life history. The young ticks are hatched in from fifteen to thirty days, and at once get on the cattle, from which time their growth is rapid, and it is during this time that they inoculate the susceptible cattle and cause the disease.—*Tennessee State Board of Health Bulletin.*

The Duties of Medical Societies.—In the account of the meeting of the British Gynecological Society which was published in *The Lancet* of July 6th, it is stated that the first business of the society was to witness three specimens: 1, that from a case of suppurating ovarian tumor with purulent peritonitis and adhesions; 2, fibroma of the uterus removed by enucleation; and 3, total extirpation of the uterus and ovaries for prolapse. With regard to the third case a few remarks are, we think, called for. The surgeon who narrated the case explained that for the prolapse he tried the use of pessaries, and not succeeding therewith he decided to remove the uterus and appendages, the patient being a woman aged thirty. We do not pretend to write as gynecologists; but we do not for that reason feel it at all less binding on us to say that in our opinion the reasons for this procedure require to be more fully set out than appears to have been done at the society. We note that the president (Dr. Godson), Dr. Routh, and Mr. Taylor, of Birmingham, criticised the procedure in a tone of disapprobation. Ordinary surgery has become more conservative with its increased powers. The removal of a leg is felt to be an unsatisfactory and opprobrious proceeding, except as a last measure of relief. *A fortiori*, any operation involving a much more serious mutilation must be so regarded, and we are of opinion that a society before which such cases are recorded does not discharge its duty without investigating the case by a committee appointed for the purpose, and placing its deliberate judgment on the facts on record. The amount of suffering and disability experienced by the woman, the precautions taken by the surgeon before operating, and the degree to which he shared his responsibility by consultation and by full statements of the facts to the patient, are obvious matters for inquiry. We gather that the operator acted with perfect satisfaction to himself in what he did, and doubtless when the full facts are known we shall find with perfect propriety. But for the sake of the reputation of surgery, and especially of gynecology, we maintain that the facts should be fully investigated and published by the society, which has in a degree incurred responsibility in connection with the case.—*The Lancet.*

A Hospital on Wheels.—One of the most novel of the recent achievements of modern philanthropy is the invention of a hospital on wheels. This evolution of the travelling van is due to the genius of a Scotchman, Dr. Wylie, of Pathhead. The advantages of the plan are many and obvious. An infectious patient can be called for and carried off bodily into the midst of beautiful scenery, where he can be nursed back into health and strength under the care of the local doctor. Under such circumstances it would be of course easy to provide for the most perfect isolation. In the middle of a moor, for instance, isolation is, so to speak, automatic and inherent. The risk of conveying infection would arise mainly during the passage of the caravan from starting-point to destination. In fine summer weather the plan is simply fascinating. A larger hospital can be made by knocking out the ends of two wagons and joining them together. The attractiveness of Dr. Wylie's *al fresco* hospital, however, would be considerably lessened or altogether lost by bad weather or by the advent of winter.—*The Medical Press.*

THE CLINICAL ASPECT OF DYSPEPSIA.[1]

By SIMON BARUCH, M.D.,

NEW YORK CITY.

ATTENDING PHYSICIAN TO THE MANHATTAN GENERAL HOSPITAL, NEW YORK.

As a disease dyspepsia fortunately disappeared from our text-books, and, perhaps, less fortunately, it is rarely chosen as a subject for society discussion. As a pathological entity dyspepsia no longer exists, but as a curse to mankind in every station of life, its existence is a sad reality, as every practical physician has ample opportunity to observe. My choice of so homely a subject for a paper before the society may evoke some criticism, which I do not hesitate to encounter. A discussion of dyspepsia may not be invested with the glamour and prestige of the grand surgical achievements with which visiting colleagues from the great medical centres are wont to regale you; the mental and physical suffering, the loss of time and money which are involved in it, and the enormous number of people afflicted by it, lend a dignity to the subject which no surgical achievements of this great surgical era may exceed. In the humblest, as in the most palatial, homes this arch fiend makes human beings miserable and sends them sooner or later to the physician. Can we dismiss these sufferers by telling them that dyspepsia is not a disease? They come to us for treatment. How can we relieve them, *tuto, cito et jucunde!* This is the pressing question for us.

It is a happy circumstance, for both physician and patient, that dyspepsia has ceased to be recognized as a disease against which our materia medica must spend the force of most of its agents. The realization that dyspepsia (δυς—difficulty; πεπτω—to digest) is a symptom or manifestation of various diseased conditions of the stomach, and not infrequently also of no *stomach* disease at all, is the most important step to its more successful management. The symptoms which may be grouped under this term are general and local. The general symptoms, *i.e.*, those affecting the entire system, are, as you well know, innumerable; there is not a disease whose "livery may not be worn" by dyspepsia. They range from the most serious psychoses (which the ancients have not inaptly termed hypochondriasis) to all those minor disturbances which are but too often erroneously grouped by superficial observers under the appellation of neurasthenia.

Moodiness leading to introspection, sluggish mental action, loss of memory, enfeebled muscular power, giving rise to exhaustion after the ordinary duties of the day, which in health were performed without effort; vertigo, insomnia, cardiac, pulmonary, and lumbar aches and pains which render the patient miserable by referring them to brain, heart, lung, and kidney diseases; headaches of various types, dyspnœa from the mildest form to the most labored respiration; intermittent pulse, tachycardia—these are some of the manifestations that may be traced to difficult digestion. These general manifestations are the chief source of discomfort and unhappiness. Which of us has not been consulted by some anxious dyspeptic, who brings a tale of woe centring around a pain in the heart, with palpitations, etc., which literally "vanishes into the thin air" when an alkaline carminative is administered? How many weary dyspeptics bring in a bottle of urine, containing a thick sediment of phosphates or urates which they interpret into kidney disease. Such cases of so-called liver disease formerly came to me almost daily when I practised in Camden, where they doubtless come to you in great numbers. Such cases crowd the consulting-rooms of the metropolitan doctor, taxing his utmost resources of tact and therapeutic skill. When they are carefully questioned and each organ is successively interrogated, the stomach often stands out as the sole culprit. A cloud is lifted from physician and patient alike by a thorough analysis of all the symptoms. As in all other diseases, a painstaking examination is the most important element in the management of dyspepsia. I shall presently show that time spent for this purpose is well spent in the interest of both patient and physician. Without asking leading questions, we may often obtain a history of abnormal sensations and taste in the mouth and fauces; loss of appetite, nausea and vomiting, a sense of fulness, oppression, distention, distress, or pain in the region of the stomach, which is absent before breakfast but more or less persistent throughout the day. We may learn of eructations of gas, acid, or water, following more or less rapidly after each meal. There may be pyrosis, nausea, vomiting, etc.

The interpretation of these symptoms of difficult digestion has passed through many phases. As it furnishes us often a clue to their management it may not be without interest to summarize briefly their conception at the present time.

1. *Loss of appetite* may be due to a sense of satiety arising from overdistention of the stomach by gases or particles of undigested food, which are retained by reason of enfeebled motor power of the stomach. In the form of repugnance to food it may be traced to that often groundless apprehension of impending gastric disturbances ascribed to almost every kind of food, which is a common observation among nervous dyspeptics. It may be well to bear in mind that in organic disturbances of the stomach the appetite is usually fair, sometimes good.

2. *Sense of fulness and pressure in the epigastrium*, which the patient usually designates as "a weight in the stomach." This symptom is readily accounted for by dilatation of the stomach and by its retention of fermenting and fermented particles of food, and gases arising from them. That gases form in the stomach in certain types of difficult digestion is evidenced, not only by these eructations, but actual demonstration of their presence has been made by reliable chemists. Formerly the idea obtained that decomposition of food and consequent fermentation giving rise to gases, only occurred in the absence of a sufficient quantity of hydrochloric acid. This error has been disposed of by Hoppe-Seiler, who demonstrated that hydrogen arising from butyric acid fermentation may be developed in the presence of two per cent. of hydrochloric acid in the stomach; but when free hydrochloric acid is entirely absent, a large quantity of CO^2 was found. The intensity and extent of the fermentation depends upon

[1] Read before the South Carolina Medical Association, April 23, 1895.

the quality or the food and upon defective motor power of the stomach, which delays the passage of digested and undigested food particles into the upper bowel, and thus renders the usual quantity of HCl in the stomach insufficient to prevent alcoholic, lactic, and butyric acid fermentation. Even decomposition, evidenced by evolution of sulphuretted hydrogen, may occur, and may be clearly recognized in the eructations. Thus may the stomach be distended and, pressing upon the diaphragm, produce a sense of oppression which renders the patient miserable and despondent, and casts a gloom over his whole life. It should be borne in mind, however, that in certain nervous dyspepsias these symptoms are present without manifest organic changes, and in a perfectly empty state of the stomach the eructations sometimes even consisting of swallowed air.

3. *Absolute gastric distress or pain* may arise from various causes. In gastric catarrh fermentation of the contents may cause so much distention of the stomach that pain is experienced which does not yield to anodynes. Pain is not, however, so frequent in this condition as in gastric ulcer or in nervous dyspepsia. The term "gastralgia," usually applied to these pains, is misleading, because its treatment is apt to be symptomatic, viz., by anodynes. A correct differential diagnosis of acute gastric pains may be obtained only by a correct understanding of its causation.

In gastric ulcer the pain is chiefly due to irritation by the secreted hydrochloric acid of the delicate nerve endings which the ulcerative process has exposed. Hence we have a distinctly localized pain of a burning, agonizing character, radiating to, and often felt in, the region of the dorsal spine; it is increased by pressure, if the latter happens to be made near the locality of the ulcer; it is aggravated by any kind of food, but more especially by imperfectly chewed solid food. Fortunately, *we have an almost certain diagnostic sign* in the efficacy of alkalies for the subdual of this kind of pain. Even when large doses of morphine have failed I have seen pain from ulcer of the stomach disappear as if by magic after a dose of magnesia. I have in mind a haggard, sallow-faced lady from San Francisco, who had come to New York to consult a noted specialist with regard to a severe gastric pain, which recurred at intervals and was sometimes accompanied by jaundice. This gentleman had examined her carefully, and concluded that there was no disturbance which required treatment at his hands. In pursuance of this opinion she had decided to return home on the following morning. This plan was, however, frustrated by the sudden illness of her child, which I was called to attend. Suffering severely one evening, she gave me a history of her case and asked my advice. I declined a positive opinion until morning, and stated that if her pains should be relieved by the powder which I prescribed for her (bismuth subnitrate and magnesia, ust. āā gr. x. every three hours), I should decide upon the diagnosis of ulcer of the stomach, and advise her to remain six weeks for treatment. If, upon the other hand, the gastric pains remained unrelieved in twelve hours, I should agree with her previous medical adviser and consent to her returning home. On the following day she was entirely free from pain, and by reason of the positive opinion expressed, she consented to remain under my care. The treatment adopted successfully in this case will be referred to later. I desire here only to emphasize the diagnostic value of alkalies. In gastric pains due to *nervous dyspepsia* alkalies would afford some relief, but not entire removal. The pain in these cases is not so distinctly localized, but more diffused; it is not acute and boring, but rather spasmodic, somewhat relieved by eructation and uninfluenced by food. It is at times so severe that a condition of collapse may ensue, evidenced by cold extremities, pallor, and feeble pulse. Such cases may be differentially diagnosed sometimes by the co-existence of a systemic neurosis and by hyperesthesia of the abdominal parietes, which not infrequently yield to deep pressure. Such attacks often resemble angina pectoris. I have seen two cases mistaken for the latter by two prominent diagnosticians in this city, and one of my own cases afforded a similar observation.

At this point a form of gastric pain may be referred to, whose early recognition is of great diagnostic importance, viz., the gastric crisis of Charcot. Its peculiarity is a periodical character, its great intensity, spasmodic type, and tendency to radiate downward and backward. The vomiting which almost invariably accompanies without relieving it, renders it characteristic of *locomotor ataxia*. At any rate, it is always safe to examine the tendon and pupillary reflexes of patients suffering from periodic severe gastric pains and vomiting. Much bootless medication and groping in the dark, which discredits the physician, would be spared by such a course.

Pyrosis or heart-burn is one of the prominent symptoms of difficult digestion. This is no longer regarded as due to regurgitation of acid fluids from the stomach to the œsophagus, for it has often been found to exist when the stomach-tube failed to discover any fluid at all. It is now regarded as a neurosis affecting the motor apparatus of the stomach.

Nausea and vomiting are not infrequent manifestations of difficult digestion. In long-persistent gastric catarrh, when large quantities of tenacious mucus line the mucous membrane, nausea is not rare; it is often the result of overdistention of the stomach by fermenting materials, being more of a gulping up of the latter than a real expulsive act. Frequent vomiting of food is a serious symptom (except in hysteria), always indicating organic changes in the stomach, the most grave of which is cancer. In the latter a long period usually elapses between ingestion and vomiting of food. Its expulsion, unchanged or decomposed, affords a clew which may be verified by other symptoms, as cachexia, malnutrition, the presence of a tumor, and the presence of lactic acid in the test-meal. Having now briefly passed in review the local manifestations of difficult digestion, and the manner in which they may aid in our diagnostic search, which is, after all, the great prerequisite to successful treatment, I desire to refer to a rapid and practical method of securing confirmation or rejection of the diagnosis obtained from the subjective signs of dyspepsia.

The number of chemical tests which have been proposed for the purpose of obtaining a reliable measure of the digestive capacity of the stomach is bewildering to the general practitioner. One by one I have abandoned them, except in obscure cases. There is a simple method which I would commend to your attention, and by which we may ascertain without much delay, and with sufficient accuracy for all practical purposes, not only the type of dyspepsia we have to deal with, but to a certain extent also the dietetic and other treatment most appropriate for the case. I refer to the stomach-tube, which is doubtless familiar to most of you. Ordinary cases of dyspepsia do not require its application; they usually yield to a properly directed treatment without much difficulty. In cases of chronic, obstinate, and long-persisting dyspepsia, however, I advise the patient to eat a good meal of mixed food, especially enjoining upon him to consume those articles which he has long avoided as indigestible. He is requested to appear at my office five hours later for examination of the stomach contents. A strong elastic tube of one-eighth to one-half inch in diameter, which is sold for that purpose, is introduced into the stomach, six ounces of warm water are poured into it from time to time, and siphoned out into a basin. In gastric catarrh the latter will contain large quantities of thick gelatinous mucus, floating upon the surface of the water, débris of food, sometimes unchanged and partly digested, which sinks to the bottom, and much foam from gases of fermentation. If after five hours much

food remains in the stomach, second and third examinations are made, prolonging the interval between eating and examination an hour each time, until eight hours have been reached. It has been definitely ascertained by Kretsch, who examined patients suffering from gastric fistulæ with the stomach-tube, that a moderate breakfast of rolls and coffee is digested in four and a half hours, a good dinner of mixed food in seven hours, and that during sleep seven to eight hours are required for the disposal of an ordinary supper by the healthy stomach.

If the patient be unable to eat a large test-meal, a smaller one, consisting of bread and tea, is ordered, and he is examined two or three hours later by lavage, in order to test the motor capacity of the stomach. If we have a case of nervous dyspepsia to deal with, *i.e.*, a dyspepsia without organic changes in the mucous lining, neither mucus nor food will be found, or these will appear in very small quantity.

This is a very simple method of diagnosis, and seems, in contrast with the elaborate chemical tests practised by our friends the gastrologists, almost insignificant. Far be it from me to underrate the value of the test-meals of Ewald and others, one of which consists of a roll and a glass of water, which are siphoned, or rather drawn out, an hour or two later, filtered and examined for hydrochloric acid, ferments, and other elements involved in the digestive act. These tests, let me urge, are troublesome and by no means accurate, or well established. Each prominent gastrologist has a method which he regards as superior to the fallacious method of his confrère. For instance, there is not, according to Ewald, at the present time a single unobjectionable or exact procedure for the estimation of the exact quantity of hydrochloric acid contained in the stomach. Again, for a long time the mere absence of hydrochloric acid from the contents of the stomach, an hour after a test-breakfast of rolls and water, was regarded as pathognomonic of cancer. Now this is proven fallacious, it having been shown that only in open ulcerative cancer of the stomach is this the case, because the secretions from such surfaces neutralize the acid. I may say, in parentheses, that at the present time the presence of a considerable quantity of lactic acid after a test-meal is regarded as a positive sign of gastric cancer. These tests may serve a useful purpose, nevertheless, in very doubtful cases, in which clinical signs are insufficient or difficult of interpretation. They may be resorted to in cities where chemists and specialists abound. But I desire to impress upon you the fact that for all practical purposes, in the majority of cases the practitioner is competent to make a diagnosis, without these tests, with sufficient accuracy to treat the patient, if he exercise care and judgment. It must be conceded that if we find, upon examining the contents of the stomach five or six hours after a hearty meal, that every particle of the latter has been disposed of, we have good reason to believe that the patient's acids and digestive ferments, as well as the motor or propulsive capacity of his stomach, are normal. This is the outcome of personal observation during a period of thirty years, before and since the modern tests and methods, all of which I have faithfully practised, came into vogue. I well remember two cases of cancer of the stomach in which the chemical signs were plain, in one of which a morning irrigation of the stomach brought out putrid detritus of a meal taken twelve hours previously. In both cases a noted specialist in stomach disease, whose good work in this branch induced me to consult him, declined to say positively, from his analysis, that the patients suffered from malignant disease. Both patients died, one after an operation. On the other hand, I have recently been consulted by a gentleman who gave a history of having been treated for several years by gastrologists. Boas had pronounced his case nervous dyspepsia; a New York specialist called it gastric catarrh and made him "swallow electrodes and undergo all kinds of torture," as he expressed it, without result. Another specialist gave him a test-meal and pronounced his case nervous dyspepsia, with poor digestive power. When he applied for water treatment, which had benefited him a year ago more than stomach treatment, I found him greatly discouraged by the disagreement of the specialists and their failure to remove his dyspepsia, to which he insisted upon being a martyr. A full dinner was ordered for him, with the injunction to eat such articles as he had avoided as indigestible, including chocolate éclairs, whose mention even horrified him, and to report five hours later. When he witnessed the irrigation of his stomach and saw no return of undigested food, the water returning perfectly clear, he exclaimed: "Now I am convinced that my digestion is normal, and I shall no longer worry myself about dyspepsia!" Such positive demonstration is more valuable than chemical tests, especially for its moral effect in those cases of nervous dyspepsia which are the bane of the doctor's life.

Treatment.—A differential diagnosis having been clearly established between gastric catarrh, nervous dyspepsia, and gastric ulcer—the three most prolific sources of difficult digestion—each disease demands a specific, distinct mode of management.

Gastric catarrh is, according to my personal observation, the most frequent cause of dyspepsia in rural districts and in the smaller towns; nervous dyspepsia bearing an equal share of prevalence with it in the larger mercantile and manufacturing centres. In discussing catarrh of the stomach, it is important to disabuse ourselves of the idea, which is but too freely adopted, that it is like other catarrhs, for instance, catarrh of the pharynx. The latter is chiefly a hypersecretion arising from inflammation of the epithelial stratum of the mucous membrane. Inasmuch as the lining membrane of the stomach differs materially from that of the pharynx in structure and function, its inflammations assume quite a different aspect. The cylindrical epithelium of the gastric mucous membrane is continuous into the gastric glands, with which it is almost imperceptibly incorporated. Hence the same epithelium practically covers every part of the gastric lining, including all its structures and glands. Gastric catarrh, therefore, always involves the latter, if it is not limited to the little elevations between the edges of the glands, which is rarely the case. A gastric catarrh is, therefore, more like a chronic nephritis in its essential characteristics than like a simple catarrhal inflammation. Bearing these crude pathological facts in mind, the salient indications for treatment should be limited to the restoration of the *functions* of the stomach to a normal standard, especially of that portion which produces the excessive secretions whose interference with the act of digestion is the chief source of trouble. The stomach, be it remembered, is no longer considered an organ of absorption, but rather is it now regarded as a receptacle for food coming into it after preparation by mastication and insalivation, which it elaborates chemically and mechanically for propulsion into the upper intestinal tract, when absorption and the first step of utilization of the food is accomplished. Not even water is absorbed by the mucous membrane of the stomach. Indeed, it is held by physiologists of repute that if well-masticated food could reach the duodenum without passing through the stomach, it would be utilized almost wholly, but that such food may irritate and eventually cripple the most important portion of the digestive and assimilative organs. The first thing to be done in treating gastric catarrh is to remove the causes which have conspired to produce it. The second indication is to assist the muscular or motor apparatus of the stomach in its work of churning, mingling, and propelling of ingesta into the absorbing chambers, by introducing only such food as may not embarrass by distending it. The third object

is the removal of the accumulated tenaceous mucus, which embarrasses the stomach glands at every point.

These being the prime indications for treatment, how are they to be fulfilled? Among the causes of gastric catarrh, the most prominent are improper food, insufficient mastication, and depreciation of the general health. The removal of these causes would, in a large proportion of cases, remove the disease entirely, but the enormous difficulty which confronts us in the attempt soon becomes apparent and discouraging.

1. Imperfect food. The subject of food and its preparation is too extensive for discussion in the limited time at my disposal. Reference to a few salient points must suffice. Saccharine and fatty food should, of course, be avoided, freshly baked breads or cakes being especially damaging. Among farinaceous foods, most of which are objectionable, rice cooked in the true South Carolina fashion, viz., by steaming so that each grain be separate and dry and not pultaceous, is the least harmful. Being exceedingly nutritious, as is evidenced by the enormous amount of physical labor endured by the Japanese and others under an almost exclusive rice diet, its constant use at one of the daily meals should be insisted upon. Excess of fluids at meals should be avoided, also all alcoholic and fermented beverages at all times. Frying is a pernicious mode of cooking, especially when fat is used to increase palatability. Boiled and broiled meats and fish, eggs, with rice and stale bread, form an ideal diet, and *hot* (not lukewarm) milk an ideal drink for meals. So much for the diet for the *prevention* of gastric catarrh in predisposed persons.

In the treatment of the established disease I limit my patients to a few articles of diet. Meat, especially beef from the round, well-chopped in an Enterprise chopper and freed from all fibre and fat, called Salisbury steak in our restaurants (after the physician who claims to cure all chronic diseases from dyspepsia to phthisis by hot water and beef); this preparation of beef is the ideal food in the treatment of gastric catarrh, because it furnishes but little *débris* and gives rise to no fermentations, hence no distentions, and is easily propelled into the duodenum. The next best food is hot milk. It should be so hot that it cannot be consumed except with a spoon, and very slowly. My usual dietary prescription in moderately severe cases is a pint or more of very hot milk for breakfast, as much Salisbury steak as the patient desires for luncheon and dinner, with perhaps a little black coffee and some Italian bread (long dry sticks) to lessen the monotony to the palate. In more severe cases I order one pint of very hot water sipped one hour before each meal, *a shorter interval renders its use futile* and interferes with digestion, the meals to consist entirely of chopped meat, without bread. Before broiling this meat Delmonico's *chef* pours the white of an egg over it, causing cohesion without packing. I have imitated this excellent device with profit. Patients will complain of the monotony of the diet, but in these cases it is the only means of feeding at our disposal and should be insisted on, gradually if necessary, but always peremptorily.

2. Imperfect mastication must be remedied. It is futile to instruct the patient in the avoidance of this prolific source of gastric catarrh, because the fault most frequently arises from thoughtlessness and habit. It is my practice to advise the patient to request those persons who are his habitual table companions, to check him whenever he is eating rapidly. Business men should be advised to eat a very light luncheon at their restaurants, because this meal interrupts their work, to which their thoughts constantly revert while eating, and thus only by the greatest self-control may proper attention be given to thorough mastication. It goes without saying that the teeth, especially in elderly persons, should be put into good condition or replaced by artificial ones. The mouth and teeth should be mechanically cleansed and disinfected several times a day by preparations like bovine or a moderately strong solution of chlorate of potash, because decomposition of ingested food may be started by the commingling of bacteria and partly decomposed food coming from the mouth.

3. Our means of removing mucus from the stomach and restoring the functions of the latter are mechanical and medicinal. Among the former may be counted the anteprandial potations of hot water referred to. I usually prescribe five grains of resorcin an hour before each meal as an antifermentative, and if hot water is not well borne or is impracticable, as in the case of business men, a powder of ten grains each of bismuth and magnesia, half an hour before meals, serves a good purpose. The most potent measure, however, for the removal of mucus and stimulation of the motor function is stomach-washing or lavage. The technique of this little operation is not difficult, but without attention to certain details failure is prone to attend it. Hence a few words on the subject may not be out of place. In the first place the tube should be made of firm, yet elastic soft rubber (hard rubber tubes are dangerous), five feet long, from one-quarter to three-eighths of an inch in diameter, with open end, one inch from which should be located a narrow fenestrum, three-quarters of an inch long. The largest size tube affording a more rapid entrance and exit of water, shortens the duration of the sometimes unpleasant, though not painful, procedure. A medium-sized or small tube with firm, thick walls, sometimes passes more readily. The patient should be protected with a rubber apron or other covering, seated upon a chair and a basin placed upon another chair, one of whose corners is wedged between the knees. The procedure should be explained; he should be instructed to breathe through the nose and open mouth, and he may be assured not to apprehend choking when the tube enters the throat, by the fact that the diameter of the tube is much smaller than particles of meat which he has often swallowed. A quart pitcher of tepid water, to which a teaspoonful of salt has been added, a funnel, and several towels having been placed in readiness, the mouth is examined and artificial teeth are removed. Bending the head slightly forward, the patient is requested to protrude his tongue, which should never be pressed out of the way. The lower end of the tube having been dipped into the water for lubrication (oil damages the rubber), it is grasped about four inches from its extremity, like a pen; the somewhat rigid portion is now gently passed into the pharynx, avoiding the tongue as much as possible. When it touches the pharynx, the patient is asked to swallow. At this moment the tube is pushed gently downward. In patients having lavage done for the first time, or who are nervous and fretful, rasping and choking will ensue. The tube should be withdrawn if this continues, and a second and third effort should be made while the patient's morale is sustained by gentle reassurance, and not by scolding. "Put yourself in his place" should be remembered by the physician, when the patient seems alarmed by this simple and absolutely harmless procedure.

In persons of calm temperament and in those who are accustomed to the tube, it will slip down easily upon gentle yet firm pressure being made, and by sliding it through the thumb and forefinger whenever the latter reaches the teeth, until the black ring mark, which is from twelve to eighteen inches from the lower end, reaches the lips. The patient, if quiet, otherwise an assistant, now holds the tube between thumb and forefinger of the left hand close to the teeth, which must not be closed. Adjusting the funnel to the upper end of the tube, four to six ounces of the salt water are poured into it, the funnel is raised to insure its outflow by gravity. If undigested food be present the water may not flow out readily, because the lower openings are clogged. In this event, raising the funnel higher may

force the obstruction out, otherwise the tube must be removed and reintroduced after clearing the fenestrum. About half a pint of water having entered the stomach, the funnel should be lowered while water is still contained in it, in order to produce siphonage into the funnel, which is now turned to allow the water to flow into the basin. This act is repeated until the water flows out clear. Some patients—about fifty per cent.—gag and vomit during lavage. These must be cautioned to hold the teeth apart and simply bend over the basin and let the vomitus flow into it, while they or an assistant firmly hold the tube near the teeth. Otherwise it will be washed out with the rushing stream. Perseverance and calmness on the part of the physician will insure against failure. Among hundreds of cases I have failed but twice, one being a nervous woman and the other a nervous physician, neither one of whom would permit a second introduction. Most patients become accustomed to the tube after two or three introductions. I remember well an old lady from Charleston, who consulted me about eight years ago for a most obstinate gastric catarrh which caused vomiting after meals, and impaired her nutrition badly. When she saw the tube she declined to have that "snake-like thing" near her. In two weeks she introduced it herself, and thus did more to complete the cure than I could have done. Indeed, there is no method of treating this disease comparable to lavage. It should be done before the chief meal once a day, in order to obtain the full benefit of this meal. If mucus accumulates rapidly and the quantity does not diminish each day after several irrigations, lavage may be done before breakfast also. Mucus is removed, the glands are freed from obstructions, the muscular power is increased by the daily filling and emptying of the stomach and removal of fermenting material, and the introduction of the foreign body increases secretion from the gastric glands.

Another valuable effect of lavage is the discovery of those articles of diet which are best adapted to each case, and in some cases also of certain defects, as in the following instance. A lady from Georgetown, S. C., consulted me several years ago for severe colics, for which she had been treated in vain by her intelligent physician at home: Close examination led me to charge her with too rapid eating and careless mastication. She indignantly repudiated the charge, saying that she was the slowest eater in her family. A test-meal of rice, beef, tomatoes, and accessories, showed particles of unmasticated meat and even some of the rice-grains were unscathed and had swollen to thrice their size. This ocular proof convinced the patient of the necessity of more thorough mastication and she recovered entirely from gastric catarrh, which was the cause of her colic, under the treatment here outlined.

The irrigations should be continued daily or less frequently, according to the reaccumulation of mucus, until the stomach remains clear for a week or two, and the symptoms subside. Contra-indication to the use of the stomach-tube are aneurism of the aorta, innominate or carotid arteries, angina pectoris and uncompensated valvular lesions, fatty heart, pregnancy, cerebral congestion, asthma, and very great debility. In ulcer of the stomach, with or without hemorrhage, lavage should be used only with the greatest caution, if at all.

I have perhaps entered into tedious detail on this subject, but my desire to offer you personal experience obtained from failures and successes, must be my warrant therefor. Among medicinal agents, benefit may be derived from twenty to thirty drop doses of dilute hydrochloric acid in four ounces of water, taken immediately before eating each solid meal. The words *immediately before eating* should be emphasized, and it must be insisted on, that the plate be served and the patient ready for the fork or spoon when the acid is taken. This I learned thirty years ago, from Dr. Thomas King Chambers, London's great clinician, and his advice has served me well. There is no other medicinal agent that is of any value in this condition, except resorcin and bismuth, already mentioned; I have gone through them all and discarded them. Pepsin I have not used at all in the last ten years, although I formerly used it freely, and found it worthless unless combined with muriatic acid. How do we know that it acts in the stomach as it is claimed to act in the test-tube. If taken before meals it is probably absorbed or expelled, before the stage of digestion for which it is intended is reached. Nor can we expect to compensate for deficiency of the natural hydrochloric acid by pouring the small quantity above mentioned into the stomach. It is more its agency as a coagulant of mucus, and as a disinfecting agent, that its good effect may be ascribed.

It is here in order to say a word about the various commercial combinations of pepsin, lactopeptine, wine of pepsin, mixed with medicinal agents, etc. It would seem that the slightest reflection would condemn the use of any and all of these. The apparent beneficial effect sometimes reported is due to the otherwise judicious management of the diet, exercise, etc., in the case. Lactopeptine, for instance, claims to be composed of several elements some of which we know would be destroyed by acid, others rendered inert in an alkaline medium. And yet many send this highly lauded conglomeration on its mission through the saliva, gastric juice, without reflecting upon the physiological incongruity involved. The more simply a case of gastric catarrh (and for that matter any disease) is treated the more successful will be its management.

The fourth therapeutic indication in gastric catarrh —*the improvement of the general health*—will be referred to at length when considering the next subject.

Treatment of Nervous Dyspepsia.—The indications in the phase of difficult digestion are entirely different from that of gastric catarrh. Instead of the embarrassment of the glandular action present in the latter, we have a hypersecretion usually, hydrochloric acid having even been found in the empty stomach of some of these patients. A detailed description of nervous dyspepsia is not required before this audience. You are all familiar with it, although it is not as common here as it is in New York and other large cities.

A diagnosis having been clearly made by the stomach-tube and lavage, the local distress demands immediate attention. For this purpose bismuth and magnesia in ten-grain doses are extremely helpful if given half an hour before meals. The postprandial pains, heartburn, and other manifold distresses, often yield to the tablets of animal charcoal, magnesia, and ginger, as made by Wyeth and others, one chewed dry every half hour. Sometimes larger doses of bicarbonate of soda and magnesia may be required. Lavage is rarely needed, chiefly when there is an accumulation of gases. A hypersensitiveness of the digestive organism exists here, which may be in a comparatively dormant state for a time, and at other times be exasperated by some special indiscretion in diet or, more frequently, of conduct. We find no organic defect, but, on the contrary, an over-active function. The aim of treatment should be to reach the cause, which is usually psychical. Close confinement to indoor work, especially in the counting-room and library, must be abandoned; the patient should be placed in closer communion with nature. Very active exercise is to be deprecated, but change of air and scene are of inestimable value, indeed, of greater value than any other treatment. When the patient cannot leave home, or is not benefited by change of air and scene, or the physician desires to insure the permanence of the effect of the latter, a course of hydrotherapy offers the best chance for him. By improving the general tone, the functional activity of the stomach and other organs is enhanced, the nutrition is improved, and in a brief

time the entire aspect of the case is changed. This is illustrated by the history of the following cases :

Mrs. O——, aged twenty-eight, resident of Florida, consulted me, May 5, 1892, for "catarrh of the stomach," because of agonizing pains after meals. She has been living on mush and milk, and has had medical treatment for several years, with diminution but not disappearance of the pains. She is emaciated ; her voice is feeble ; she is depressed and hopeless. Her wan face and prematurely old appearance bear evidence of a life of constant physical suffering. There is not a particle of the hysteric element in this case. Ordered at 12.30 P.M. a full test-meal at Delmonico's, which she reluctantly accepted, because of dreaded increase of pain. The stomach was washed out without difficulty five hours later. To her great surprise, my prediction that her dinner would be digested was verified, a little tomato peel being the only remnant visible. The diagnosis of a gastric neurosis being thus confirmed, she was ordered a mixed diet, chiefly consisting of hot milk and stale bread and hominy for breakfast, adding eggs (soft boiled) later. Same with chops or oysters for luncheon, and steamed rice and roast beef for dinner. Desserts and salads were forbidden. The *general invigoration of the entire system* being the chief element in this case, she was placed upon daily hydriatic measures, adapted to her case by gradually accustoming her to lower temperatures and stronger pressure. Under these she steadily improved.

June 20th.—Pain returning, the constant current, 12 milliampères, was applied by a large, flat, sponge electrode over epigastric, and a small one over lumbar, region.

June 27th. — Temperature of baths having been higher, was now reduced, patient being again depressed. The jet douche was given at 50° F. for thirty seconds ; reaction good.

July 9th.—Electricity having been unavailing, and fermenting material being found in the stomach, the Scotch douche was applied to epigastric region for thirty seconds after the rain bath, 70° to 45° F. daily, and followed by jet douche at 50° F. for thirty seconds. Patient now feels sufficiently restored to go to Buffalo to her parents.

Under date of November 26, 1892, she writes that she has gained fifteen pounds in weight and is much stronger ; has continued the diet prescribed, because, like most of these neurotics, she "feared her stomach was not equal to much of a change." Most of the time she is entirely free from pain ; she has slight distress every now and then, but expresses the warmest gratitude for the help given.

Miss W——, daughter of an Ohio physician, aged twenty-three, was sent to me by Dr. Francke Bosworth, the well-known rhinologist, on May 15, 1889, pale, emaciated, despondent, the picture of woe and despair. She was brought into my office by her sister. She had been ill three years, suffering first from fainting-fits at the menstrual period, afterward from violent pains in the right hand, traversing the body and concentrating in the epigastrium. For these her father and brother had been compelled to administer morphia for a month. Her stomach became irritable, and has continued so up to the present time. She vomited or spat up nearly all her food, mostly the solids. Seabaths did not improve her. She studied hard and grew worse. In the fall of 1888 she lived on milk and farinaceous mush, and her stomach was regularly irrigated, without improvement. She grew worse, became emaciated ; took peptonized mild for a month, but vomited it ; meat produced the same effect. Last fall she lived on grapes, which agreed with her. Now, she had tonics, and pepsin, and all possible medications which her father and brother could muster. She was sent to Dr. Bosworth, who is a friend of her brother. After being in the city for three weeks without improvement, the doctor sent her to me. She now vomits every day. She traces her ailment to painting-lessons, but I drew from her the history of a potent psychical factor as a cause—the sudden, violent insanity of the favored nurse of her childhood. My diagnosis was nervous dyspepsia. The stomach was washed out twice a week to remove mucus and fermenting material. She had general faradization daily. Every morning she received the dripping sheet at 60° F., while standing in warm water, and other hydriatric measures as she progressed. Under this systematic management she improved slowly ; vomiting ceased entirely. She went to the seaside ; improved in July. On her homeward journey she called to tell me that she had grown stout and felt perfectly well. A year later I received a letter from her, informing me that despite family troubles, which necessitated her adopting teaching as a means of livelihood, her health had been perfect. "You would not know me," she wrote, "as the same girl you treated."

Dr. H—— asked me on March 4, 1890, to give him lavage. He looked haggard ; suffered from migraine ; had worked hard in country practice on Long Island for years ; vomited often, with headaches ; had tried everything, including rest for eight months ; dieted very carefully, and recently, under one of our most eminent consultants, who regarded him as suffering from gastric catarrh, confining himself to hot water and chopped beef without avail. He had section of the external rectus done on both eyes by an enthusiast on that subject ; thought he was astigmatic, which Dr. Carl Koller did not concur in. My diagnosis of nervous dyspepsia was confirmed by lavage, which showed perfect digestion of a full and varied meal taken five hours previously. A mixed diet was ordered, which, together with judicious water treatment, relieved him greatly. I have recently seen the patient in consultation at his home, and found him much improved in flesh ; his general health is good and is maintained by continuing the daily hydrotherapy which I had prescribed for him, and by visiting his patients on a bicycle in the summer. He thinks he would have died if he had continued his former professor's advice to live on meat and hot water.

One of the chief difficulties in these cases of nervous dyspepsia is the dread of infringement upon what they have been led to regard as dietetic rules. The moral effect of lavage is marvellous in these cases, inasmuch as it enables us to build up the nutrition and thus improve the general health upon which the local disease seems to depend in most cases. Owing to the lack of time, too much of which I have already occupied, I will not here detail the methods of hydrotherapy indicated, save to say that daily ablutions with water at 85° F., reduced one degree every day, the patient standing in a little warm water, is a good domestic measure, and may be followed by daily cold effusions with advantage, and afterward by institution treatment where the temperature, pressure, and duration may be applied with precision.

In obstinate cases of dyspepsia, be they "catarrhal" or nervous, referred to me by colleagues after trial of all known remedies, as illustrated by the case of Dr. H——, a judicious water-treatment rarely fails.

The most rare source of dyspepsia is gastric ulcer. As in other gastric affections, a clear diagnosis, based on the presence of great pain, hemorrhage, and difficult digestion, should precede treatment. In these cases the stomach-tube is inapplicable, even when symptoms of fermentation seem to demand it. Kussmaul has devised a valuable method of treatment, which is but the outcome of common sense, because the great desideratum of all traumatic conditions, rest, is best secured by it. In very severe cases, in which vomiting and great gastric tenderness are present, the stomach should be kept undisturbed even by water. Pain may be subdued by lime-water or bismuth in large doses. Fleiner and others give, with benefit, as much as 75 to

100 grains as a dose suspended in water. I use 30 to 40 grain doses with or without magnesia. Rectal enemata of Leube's beef solution, liquid or solid peptenoids (Arlington Co.'s), and two eggs with fifteen grains of salt in two ounces of warm water, always given after rectum has been washed out, will sustain the patient during the first days. But the cardinal remedy for gastric ulcer is milk and lime-water, equal parts, given warm every two hours, beginning with two ounces and increasing gradually until a pint or more is taken, at each meal, slowly sipped with a spoon. I have seen six quarts consumed in one day. A nurse should always guard the patient against intruders; members of the family should be kept away; perfect, absolute rest is essential. The patient should not move out of bed for any purpose. All entreaties for other food must be resisted. This is the simple, efficient treatment for the first two or three weeks. Gradually farinaceous gruel, then broth, may be given, always followed by several ounces of lime-water. Carlsbad salts may be used advantageously as a purgative every other day.

The general condition should be carefully looked after. Most of these patients are anæmic. Judicious ablutions with gradually reduced cold water, gentle friction of the extremities, exposure of the patient's face, the body being well protected in a well-ventilated apartment all day, will do more to remove the faulty hæmatoses than iron, which cannot be tolerated. The quantity of milk which these patients may take with lime-water, despite their protests in the beginning of the treatment, is marvellous, if it be administered systematically. The little woman from San Francisco referred to in the early part of this paper, reached six quarts daily, despite her claim that "it always made her bilious." Sipping it slowly with a spoon, she occupied from five to fifteen minutes on each pint. A good nurse is essential. The disease is serious and the treatment demands attention accordingly. After recovery, a general tonic regimen, in which hydrotherapy always plays the most important *rôle*, is of great value, as it is in all chronic dyspepsias in which the nutrition has been depreciated.

Conclusions.—In the presentation of these views it has been my aim to remain strictly practical, and to offer the most available methods of treatment only. I trust that the following has been demonstrated:

1. Dyspepsia, though not a disease *per se*, demands the utmost interest of the physician.

2. A clear diagnosis of the source of the various manifestations of difficult digestion offers the only guide to successful treatment.

3. Few cases of dyspepsia will be encountered which resist a judicious management based upon correct diagnosis and simple treatment of the local and general conditions, especially of the latter.

Hospital Advertisements.—The London *Times* of July 23, 1895, contains the following:

"Anybody in London having spare time on Monday, 22d, or Tuesday, 23d, July, is invited to visit the Poplar Hospital for Accidents between 2 and 7 o'clock.

"Newly built. Newly fitted. No debt. No horrors. No infection.

"Best Way.—Drive or bicycle, 45 minutes from West End.

"Another Way.—Blackwall Omnibus from Piccadilly Circus, 75 minutes.

"Another Way.—Train to Aldgate, thence by yellow tram."

A Helmholtz Tablet.—A memorial tablet in honor of Professor Helmholtz has been affixed to the house, No. 8 Haditzstrasse, at Potsdam, where he was born in 1821.

TRAUMATIC SEPARATION (COMPOUND) OF THE LOWER EPIPHYSIS OF THE FEMUR.[1]

By A. H. MEISENBACH, M.D.,

ST. LOUIS, MO.

PROFESSOR OF SURGERY IN THE BARNES COLLEGE OF MEDICINE.

The separation of the lower epiphysis of the femur is so rare an occurrence when compared with other lesions of the thigh bones, fractures of the shaft, extremities, and dislocations, that every additional authentic case deserves to be reported. I say authentic, because there is room for error of diagnosis in these cases, especially in cases that are not compound. In simple cases (without rupture of soft parts and protrusion of the bone) this injury may be confounded with supra-condyloid fracture of the femur, or, possibly, a dislocation of the femur (knee) backward. In compound injuries mistakes in diagnosis cannot easily occur, on account of the form and character of the protruding bone. Surgical text-books afford a very meagre description of this injury. The report of a case that came under my observation recently, and the specimen I herewith present, is of interest.

On March 28, 1895, W. P——, aged eleven, had his left leg caught in the wheel of a vehicle. The boy distributed an evening newspaper by means of a horse and cart. He had a habit of putting his foot on the spoke of the wheel and then starting the horse, letting the wheel elevate him to a level with the body of the cart and then jumping into the vehicle. On this occasion he must have slipped: missing his hold with his foot on the spoke, his leg was pushed between the spokes of the wheel and the body of the cart so as to give it a severe wrench. He was brought to the office of my friend, Dr. Benno Bribach, who, on removing the boy's trousers and recognizing the severity of the injury, called in Dr. Voelker, and they together, with great difficulty, reduced the dislocated epiphysis, having first placed the boy under the influence of chloroform. The femur protruded about four inches through a wound on the outer side of the popliteal space. The arteries were intact. The wound was treated antiseptically, partly stitched, a drainage-tube introduced, and the limb placed on a temporary posterior splint. I was called in consultation, and the next morning at eight o'clock I saw the case with Drs. Bribach and Voelker. During the night a few small doses of morphine had been given, and the boy had rested pretty comfortably in consequence. The temperature was good, 99.5° F.; pulse, 103, full and strong. The anterior and posterior tibial pulse was also full and strong; the dislocation had been perfectly reduced.

I had been called especially to discuss the advisability of an amputation. Up to this time the boy had shown no evidence of shock. Taking into consideration the fact that the separated epiphysis had been perfectly reduced and that there was no evidence of injury to the vessels, also the patient's general good condition, I did not favor amputation under such circumstances, but that the limb be placed in a permanent dressing and that we then await developments. This was agreed to, and at three o'clock we met again to put the limb in a plaster dressing.

On my second visit I found a change. Shock had begun to make its appearance, the pulse was increased in frequency and of weaker character, but still perceptible in both tibial arteries. The plaster dressing was applied, but the condition of the patient became worse in spite of stimulants and the hypodermic use of strychnine. He did not rally from the shock and died within forty-eight hours after receiving the injury.

Autopsy.—A post-mortem examination was allowed, but not as satisfactory a one as I should have liked, *i.e.*, a complete dissection of the parts. I found the sepa-

[1] Read before the Missouri State Medical Association, Hannibal, Mo., May 21, 22, 23, 1895.

rated epiphysis completely reduced and had considerable difficulty to evulse the femur so as to separate it. The femur was stripped of its periosteum for about four inches. The soft parts of the popliteal space were much lacerated. The knee joint was not involved, the capsule was intact, which was shown by an absence of effusion of blood in the joint. The separation from the shaft was perfectly smooth, no splinters being attached to the epiphysis, as has been found in some cases.

A feature that is of interest in these cases of traumatic separation of the lower epiphysis of the femur is the direction of diaphysis. In the majority of cases, either simple or compound, the diaphysis is dislocated backward and impinges on the vessels and soft parts of the popliteal space if simple, and if compound perforates the soft parts, as in this case. In pathological separation the opposite frequently obtains, *i.e.*, the diaphysis is dislocated forward, as is shown in a case reported by myself.[1]

In traumatic cases the factors that favor dislocation of the diaphysis into the popliteal space are, 1, the character of the force applied; 2, the resistance of the parts as determined by anatomical structures.

The character of the force is usually rotatory or twisting, with a long leverage exerted by the limb, either the proximal or distal extremity of the limb as a fixed point. The anatomical structures on the anterior aspect of the thigh are more resisting, the quadriceps, tendon, and patella offering greater resistance than the loose tissues of the popliteal space, especially so during the reception of the injury, when there is a probability that the muscles on the anterior surface of the thigh are in a state of contraction in the effort, possibly, on the part of the patient to avert the coming injury. Then, also, the position of the patient is a factor, as in many cases of traumatic separation the patient is in an upright or semi-upright position, which, along with the direction of the force and the resistance on the part of the tissues of the anterior part of the thigh, will tend to push the separated diaphysis into the popliteal space.

In pathological cases, as I have shown in the case referred to, the processes that favor separation are gradual and the forces exerted different. The explanation of the manner in which it takes place is, to my mind, the following: The shaft of the femur, at the epiphyseal line, is the seat of an osteomyelitis. The surrounding structures, especially the joint, may be either specifically or non-specifically involved. We know that flexion of the joint, especially of the knee, takes place whenever there is inflammation in or about it for any length of time, if not prevented by apparatus, such as splints, methods of extension, etc. This takes place, and as the case runs on ankylosis (temporary at first) occurs, with the knee in a flexed position. By the time separation occurs the knee is pretty firmly ankylosed. Granting, now, we have separation of the epiphysis, the leg cannot be elevated by the will of the patient, the thigh being only partially under the control of the will. The leg is not supported except imperfectly by pillows, the occasion to move the patient perhaps frequent. Now, whenever the leg is raised the condyles, being fixed to the tibia, move with it. Owing to the angle that the tibia occupies to the condyles whenever the leg is elevated, the epiphyseal line of the condyles is depressed into the popliteal space and favors the slipping of the end of the femur upon the trochlear surface of the condyles. The action of the thigh muscles, which are attached to the head of the tibia, draws the head upward with the condyles so that the femur overrides the same. The action of the muscles attached to the neck and trochanters of the thigh bone also elevates the end of the femur and favors its overriding the trochlear surface of the condyles.

A peculiar feature in the case I have reported is the late appearance of the shock. In surgical cases, ordinarily, the shock is present at once or very shortly after the injury; in this case it made its appearance about fourteen hours after the injury. This is termed "delayed shock" by some authors. The explanation of this form of shock is still very unsatisfactory to my mind. Some say it is due to "reactionary mental exhaustion,"[1] others ascribe it to "commotio cerebri,"[2] or "delirium traumaticum or nervorum."

Packard[3] has collected over sixty cases of this injury, including a case of his own. In looking over the literature at my command, I have not found any additional cases reported since then (November, 1890). In an analysis of the cases reported, Packard has found that in an average of forty-five cases the average age was a little over seven years. The youngest was eighteen months, and the oldest eighteen years. The fact that it has occurred as late as the eighteenth year becomes patent when we remember that the lower epiphysis does not join the shaft (ossification) until the twentieth year.

As to sex, he found nine to have occurred in girls, three of which were caught in wagon wheels. As to causes, he shows that in the majority of cases the injury was produced as in the case I have cited, by entanglement of the limb in a moving wheel. In two instances the leg was caught in a moving cable. In five cases the injury was produced by surgical procedure, as for correction of ankylosis and deformities. One case is reported where the injury was produced by traction on the leg of a child during birth. Another case where the injury was produced by a fall in a patient of sixteen, who had ankylosis of the knee. From the above cases we see that it usually takes a great force, and this force exerted in a particular direction, to produce this injury. Either the lower leg or body is a fixed point and the exertion of a long leverage of the movable portion of the limb at the same time, the force at right angles to the limb and of a rotatory or twisting character.

In the case I have reported there was also a stripping off of the periosteum from the diaphysis, as was observed in many of the other cases by Packard and others. In my case, also, the vessels were uninjured, otherwise the tibial arteries would not have performed their function up to the time of death, but would have shown evidences of injury soon after the injury was received.

How shall these cases be treated? This is an interesting and important point. In the cases reported, we find the following procedure to have been employed: Primary resection of the diaphysis; primary amputation; reduction successfully accomplished; secondary amputations. In Packard's report we find that amputation was performed twenty-eight times; twelve primary, nine secondary, seven times not stated.

Resection of the shaft was performed in four with complete success, one doubtful result, the others not stated. Resection of the knee-joint was done in two cases, afterward followed by amputation. In the cases where amputation was done primarily, the limb was destroyed or the blood-vessels injured. Secondary amputation was done for gangrene, and abscess reduction was accomplished in fourteen cases, one of whom died on the fifteenth day of sepsis.

From the methods of treatment in the cases reported, I believe we can find the course to be pursued in the treatment of these cases. In each case the condition of the blood-vessels should be determined. This, in conjunction with the condition of the soft parts, and the practicability of reduction, must be the guidance for our procedure. Where the blood-vessels are destroyed amputation, of course, is the only resource. If

[1] Roberts. [2] Tillman.

[3] J. H. Packard, Philadelphia: Annals of Gynecology and Pediatrics, November, 1890.

the blood-vessels are intact and reduction can be accomplished, this should be done. The blood-vessels and soft parts being in good condition and reduction under anæsthesia still difficult, resection of the end of the shaft should be done, cutting away only so much as to favor reduction. Resection of the knee-joint is indicated only where the blood-vessels are twisted and the joint involved to such an extent that complications in the after-treatment may arise.

It goes without saying that all of these procedures are accomplished under the most rigid antiseptic precautions. Immobilization, by means of a posterior splint or plaster-of-Paris, should be employed.

Pulmonary Anthracosis.—Dr. Tripier, of Lyons, combats the idea that anthracosis of the lung is in any sense a specific disease peculiar to miners, and advances arguments to prove that this condition is simply pulmonary tuberculosis modified by the special circumstances of the case. (*The Lancet.*) His view is as follows: "The phthisis of miners is simply of a tuberculous nature, but predominantly fibrous, in which the carbonaceous infiltration of the pulmonary tissue, especially as regards pathological products, may be so abundant as to cause the lungs to assume such a peculiar aspect as sometimes to render difficult of recognition the tuberculous lesions thus more or less concealed by the accumulation of the carbon." He believes that when animals are made experimentally to breathe air full of particles of carbon the lungs are simply found surcharged with these particles, but without the inflammatory lesions and scleroses characteristic of pulmonary anthracosis, and that when miners succumb to accidents their lungs are found in a similar state, but without evidence of tubercle. In spite of these facts which Dr. Tripier regards as well known, he states that there is a tendency to describe pneumokoniosis (pulmonary antracosis) as an independent malady produced by the inhalation of particles of coal, silica, or oxide of iron. The object of his communication was to bring forward some pathological evidence in support of his own view. In one of his cases the patient had succumbed to "la phthisie charbonneuse," and on post-mortem examination the lungs were found to be full of particles of carbon, and much sclerosed, but further examination demonstrated the existence of a cavity at one apex and the presence of caseated tubercle. It is possible, of course, to argue that the tubercle was a secondary result of the infiltration of the lungs with particles of carbon. Dr. Tripier combats this view. In the case in point the patient had worked for fifteen years in mines without developing any pulmonary lesion, and had ceased from this occupation for six years before showing signs of commencing disease of the lungs. In a second case brought forward by Dr. Tripier, the patient had breathed a carbonaceous atmosphere for thirty-one years without any pulmonary trouble, and finally succumbed to cancer of the stomach. On post-mortem examination the lungs were found to contain particles of carbon widely disseminated, and specially numerous in the lymphatics, but without any sign of tubercle. The writer further argued that the amount of carbonaceous infiltration of the lungs bears no relation to the probability of finding tubercle. The latter may be found in miners with little or much carbon in their lungs, and in those who have spent few or many years in occupations involving the constant respiration of carbonaceous particles. Cases such as those brought forward by Dr. Tripier are, of course, inconclusive, but they must be allowed reasonable weight. They certainly tend to corroborate the view that pneumokoniosis or pulmonary anthracosis is not an independent affection with a definite cause and definite natural history, but simply one of the many varieties of pulmonary phthisis.

SIMPLE MELANCHOLIA.

By HIRAM ELLIOTT, M.D.,

WOODHAVEN, N. Y.

SIMPLE melancholia may be defined as that disordered condition of the mind in which there is a predominance of subjectively arising painful emotions accompanied by more or less weakening of the inhibitions and lowering of the moral tone of the individual, but in which the perversion of the understanding and narrowing of the range of intellectual action do not obtain in sufficient degree to constitute actual delirium or stupor. I am aware of imperfections in this definition, but it will serve the purpose of this paper.

Painful emotions are not necessarily pathological. The normal mind is capable of suffering, and the most intense and prolonged mental anguish may be in itself entirely physiological. Indeed there are many sensitive and impressionable people whose nervous structures always react violently to stimuli of a disagreeable and irritating nature. These unfortunate individuals readily surrender their minds to the control of painful emotions and their inhibitions readily give way. For example, the neurotic mother is thrown into a most painful mental condition by the death of her child; she can neither eat nor sleep; she is practically oblivious to her surroundings; she gives herself up to useless lamentations and is wholly unreasonable. But this is not melancholia, and indeed bears no necessary relation to it. The emotional states described arose objectively and out of adequate and immediate causes, and though excessive were still physiological. And it is only when such states are sufficiently severe or prolonged or oft repeated to cause the brain to take on that disordered action which is the essential underlying condition of all mental alienation that they even stand in causative relation to melancholia.

Normally stimuli of an unpleasant nature passing into the emotional cerebral planes there excite those corresponding cerebral states which are necessary to the production of mental pain, and which after the withdrawal of said stimuli soon disappear, leaving behind only their more or less distinct registration in memory. But some brains are so vulnerable, so plastic, so to speak, and possess such low reactive power that these states tend to persist pathologically after the stimuli are withdrawn, not only to continue to present the old painful sensations, but also, by extension into other areas, to develop new ones subjectively and independently. And at the same time the representative power of the brain is interfered with, fresh incoming stimuli are interrupted or distorted, they are misrepresented to the mind, and hence convey the idea of an altered environment.

Corresponding to this over-activity in the emotional cerebral plains is a condition of depression in the intellectual. The intellectual side of the brain is overwhelmed and overshadowed by the emotional and held in abeyance. The attention is weakened and incoming stimuli either fail of recognition or tend to pass over the intellectual spheres and into the emotional; and the cells of ideation being deprived of their accustomed and necessary stimulus to activity lie stagnant; and their energy, thus confined, like constrained positions of the muscles, gives the idea of an all-pervading resistance or opposition. The so-called muscular element of thought is weakened, and the mind, in measuring the resistance of the environment, over-estimates it.

For this reason melancholiacs complain that they can no longer concentrate their thoughts; that when they attempt to think or act some power seems to restrict or clog their efforts. In conversation they stop in the middle of their sentences as though the cells of ideation acted with too much friction, or as though the stimulus to their action was suddenly withdrawn, or the cells themselves overtaken with sudden weakness.

They complain that their brain is tired or congealed or worn out: they sigh and manifest many symptoms similar to muscular weariness.

This intellectual torpor, coupled with the feeling that the environment is altered as already described, disqualifies the individual to comprehend his surroundings. Nothing appeals to him except such matters as contribute to his sense of wretchedness, and he thus acquires suspicions and fears and ideas of persecution out of an environment which he sees only through the shadows of his emotions and therefore no longer clearly understands.

Corresponding to, and arising out of, this emotional domination of the mind is a weakening of its inhibitions. Of the stimuli which crowd in upon it from all directions the healthy mind is able to select a certain few to be registered in the brain-cells, and to reject the others. Indeed the education and refinement of the faculties depend not more upon the accumulation of desired cerebral impressions than upon the exclusion of the undesirable by the inhibitions. Conduct and character, too, depend not more upon the activity of those faculties and propensities which are manifest than upon the inhibition or holding in abeyance of others which do not appear. We may not be aware of the inhibitory effort, but it exists though sunk into unconsciousness.

In conditions of mental alienation, however, the seemingly changed color and altered behavior of the environment already described, and the fears and suspicions which consequently arise are so startling and obtrusive that they force themselves upon the attention, and the mind is no longer able to exclude them. It is operating under new conditions, new and strange elements are entering into the intellectual life which do not readily submit to control. Propensities and peculiarities hitherto held in abeyance burst through the weakened inhibitory barriers and more or less altered and intensified run riot: and thus a new and anomalous personality is developed very unlike the original in outward appearance possibly, but astonishingly similar to it in intrinsic qualities. There is mental derangement in the strictest sense of the term, and out of the resulting disorder certain propensities and characteristics hitherto existing come to the front and predominate. Thus one woman loses her child and falls into melancholia, another loses hers and develops acute mania, the mania determining conditions pre-existing wholly in the individual.

Further the inhibitory strength in a great measure determines the degree of mental reduction possible. Extremely sensitive emotions may coexist with strong inhibitory and intellectual power. The emotional cerebral planes may be very impressionable and vulnerable while the intellectual side and the inhibitions are correspondingly potent. In such brains there is great capability of suffering, but also strong resisting and reactive power. Painful emotions, with their attendant throng of gloomy fears, suspicions, and fancies assail the individual; he loses much of his interest in life, he becomes erratic in his demeanor, he meditates upon, plans out, and often executes schemes of suicide as ways of escape from his torture, but his judgment for the most part retains its integrity. Cellular activity in the intellectual planes may be labored or interrupted, but the product is essentially genuine. Such an individual, under proper exciting causes, falls into simple melancholia because his cerebral make-up predisposed him to this form, and is such as to render him extremely unlikely, and probably incapable, of taking on any other form.

Pathology.—Investigations into the pathology of simple melancholia have so far not been attended with very satisfactory results, for the reason that post mortem material is not very abundant, and because there is no certainty that the slight pathological conditions obtaining in life, especially in recent cases, retain their characteristics after death. That changes in the nutrition in the brain-cells will cause anomalies in the manner of their functioning seems plausible, and hence abnormal action of the vaso-motor nerves in the muscular coats of the cerebral vessels, by producing irregularity in the blood-supply to the various areas of the brain, and in this way interfering with the uniform nutrition of these parts, probably best explains the symptoms in life and the scanty post-mortem findings in these cases. Certain it is that the brains of persons who have suffered from this malady for a number of years, and who have fallen into terminal dementia reveal evidences of prolonged congestion in certain areas, and also certain other areas where the gray matter is thinned either from lack of proper nutrition or disease.

Cause.—The conditions predisposing to simple melancholia are eminently hereditary. By this we mean not so much that the parentage was insane, but that the brain of the individual in question possesses some innate vulnerability, some inborn tendency to inharmonious action of its parts, which renders it prone to take on disordered or pathological action. Drunken or vicious or phthisical parentage, but in which no insanity appears, may beget offspring with a decided predisposition to melancholia, and, in fact, to all forms of mental alienation. Again, the parents may merge a common peculiarity or weakness which appears in an exaggerated form in the offspring. Careful study of the family history of persons suffering from simple melancholia will rarely fail to find in it a weak spot somewhere, and it is always to be remembered that the denials of the patient and his friends regarding insane parentage are no sure proofs of its non-existence.

Again, the bringing up of an individual may be a strong predisposing as well as an exciting cause of this malady. Many a mother constantly drums into the ears of her children that they are delicate and nervous, and objects of commiseration, some day to discover that her doctrines have been imbibed to a degree of fidelity which more than fulfils her intentions. Her children feed on her morbid sympathy until it disgusts, but still seems essential to their existence. I call to mind one case of melancholia in which a careful study of the possible causes left little doubt but that the patient's bringing up was almost, if not entirely, responsible for her condition. This patient took special delight in biting her arms and otherwise wounding herself when in her mother's presence, for the sole sake of the horror it caused and the deluge of morbid sympathy which she knew was sure to follow.

Of the exciting causes the first and chief are disordered conditions of the general health. Whatever tends to lessen or vitiate the blood-supply to the brain weakens its resisting and reacting power and tends to depress it. Many persons indeed are so sensitive that slight physical weariness or hunger produces a marked falling off in their buoyancy. Uterine troubles in women and prostatic troubles in men are very fruitful causes of melancholia. These maladies so harass the sensitive patient that they absorb his attention, they undermine his health, and thus increase the vulnerability of the nervous system, and, in short, assail the predisposed brain in every possible way, and rarely fail to induce in it disordered action. In the consideration of this subject there is no point of so great importance as a full appreciation of this relation, which in such a vast majority of cases exists between morbid mental states and disordered conditions of the general health. If other exciting causes are to be named, domestic infelicity in women, and business worries in men, take first rank.

Course and Symptoms.—The onset of this trouble is usually very gradual and insidious. It often exists for a year or more without being noticed by intimate friends or relatives, or even the family physician. An attempt at suicide, successful or otherwise, is a rude,

but often the first, awakening of the friends to the real condition, and at the same time affords an explanation of many peculiarities in the patient's manner and conversation, which are recalled upon a retrospect of the case.

An indefinite sense of ill-being, a constant feeling of weariness, which rest and sleep do not relieve, a disposition to frequent sighing and gaping, flagging interest in life and business, unwonted irritability of temper, growing incapacity for, and disinclination to, prolonged exertion of any kind, especially mental, are among the first symptoms complained of. Sleep soon becomes uncertain and unrefreshing, and patients say that they always awaken with a sense of impending danger. In these waking moments their sluggishly acting minds do not quickly grasp and understand the environment, and hence fear it. Appetite and digestion partially fail, and the patient becomes anæmic and thin, and his expression haggard and anxious. His pupils are often widely dilated, his tongue is large and flabby and indented by the teeth, and his bowels are usually obstinately constipated.

Soon the ever-present and harassing mental pain so absorbs his attention that the patient forgets his refinements and becomes rude and uncouth in manner. The actions of his friends, seen through the shadow of his emotions, seem to him to contribute to his distress, and hence he treats those friends gruffly, or avoids them entirely. His suspicions lead him to watch the actions of others very narrowly, however, and he is often a veritable spy, and his knowledge of that part of his surroundings which is none of his business is frequently surprisingly complete. If he has any physical disease he goes over his symptoms again and again, and curses the fate that has afflicted him. As his malady becomes more chronic he usually becomes very profane; beginning with expressions of disgust, as his inhibitions weaken, he soon indulges in fits of the most impious cursing. These chronic cases soon acquire the habit of making odd grimaces and queer motions. One patient of mine delights with wetting her fingers with spittle and rubbing them over everything handy. This same patient will speak to you pleasantly and pretty intelligently, but the instant your back is turned she will make wry faces and give you a tongue-thrashing in an audible undertone and abundantly spiced with profanity.

Notwithstanding their peculiarities and constant depression these patients are often great readers, and keep fairly well posted on the news of the day, and sometimes even attend to their business in a fairly intelligent manner throughout the whole course of their disease. Although they frequently maintain that their friends have turned against them, yet when cornered they admit the foolishness of their assertions, and, in short, their judgment seems too sound to permit them to harbor delusions. Hallucinations of the various senses I have not seen in these cases. Another peculiarity of these patients is their tendency to form the drug habits. They are usually inveterate medicine-takers, and, sooner or later, they experience the pleasing sensations produced by such drugs as opium and chloral, to fall a ready prey to their seductive influence. Some take to whiskey or cologne, or, in short, anything that stimulates.

As to termination, simple melancholia usually ends in one of four ways. First, in recovery, a large proportion so ending if treated early and properly. Second, in death by suicide. And here I must assert that there are very few persons suffering from this disorder who do not early in its course contemplate or attempt suicide. Their lowered *morale* and weakened inhibitions in a great measure remove their scruples against such an action, and lessen their ability to keep in the background the constantly arising idea that death would end their misery. And their reason remaining practically intact, they plan out the most elaborate schemes for the accomplishment of their purpose, and give the most convincing arguments for its justification. Very recently a patient suffering from this malady handed me a loaded self-cocking revolver, which she had obtained, and had in her possession for some time, notwithstanding the vigilance of her friends. She remarked that she had placed it to her temple many a time, but that it was one thing to contemplate suicide but quite another thing to do the act. Cowardice prevents more suicides than all other agencies combined. Third, this disorder may terminate in the more profound forms of insanity, but this is exceptional unless drug or vicious habits are formed. And, fourth, in the chronic condition, which may, or may not, end in terminal dementia.

Illustrating this last method of termination allow me to cite the case of Mr. L——. Family history good. Following an attack of measles, at the age of twenty-two years, this man became depressed; he early developed morbid fears and suspicions and a tendency to suicide. He was a bright and intelligent man, and spoke freely of his condition. He said that all his mental actions were carried on with effort, a constant weight of misery rested upon him, and he saw nothing in life to live for. He was a great medicine-taker, and at one time attempted suicide with "Perry Davis's Painkiller," after which he cursed himself by the hour for being such a fool as to try to kill himself by swallowing hell-fire. Outwardly, he was a very religious man and a prominent member of his church, and a pretty good and useful citizen. He frequently made arrangements to take his life by hanging, but always ended with a fit of cursing at that cowardice which prevented him from putting an end to his misery. This condition of depression, according to the reliable testimony of his brother, and my own observation for the last fifteen years of his life, lasted for forty years, during which time he made a living for himself and family, and died at the age of sixty-five of consumption, without showing any marked signs of dementia beyond the acquisition of many queer habits, such as grimacing, licking his finger-tips, and giving vent to grunts of disgust and an occasional oath.

To illustrate how slight is the tendency for simple melancholia patients to fall into the more profound forms of mental alienation, even under strong exciting causes, I will cite the case of Mrs. B——. A delicate woman, with strong hereditary tendencies to insanity, in fact, her insane mother was living in the same house with her, intelligent and refined, fell into simple melancholia a few months after the birth of her second child. She was mildly depressed, and held very dismal views of life, but never evinced any real delusions or hallucinations. She took very little interest in her children, was petulant and irritable, and resented the well-meant attentions of her sister, who took care of her. She suffered somewhat from indigestion, constipation, and insomnia. She early showed a tendency to suicide, and planned out several schemes for its accomplishment, of which one was unique. Getting up in the night she roused her mother, who was so depressed and stupid that she rarely spoke and had to be dressed like a child, and the two slipped out of the house, and securing a step-ladder from the basement, walked half a mile to a reservoir, climbed over the fence surrounding it by means of the step-ladder, discussed suicide by drowning, and decided that it was too horrible and returned home. A few nights afterward they repeated their journey, and again their courage failed. The third time they made the experiment with better success, for when they reached the water's edge they jumped in together. The helpless old lady sank without a struggle, while the shock of the cold bath brought Mrs. B—— to her wits, and she was glad to be able to scramble out and hurry home to inform her sister what she had done.

Notwithstanding this terrible shock and the full con-

viction that she was mainly instrumental in causing her mother's death, sufficient one would think to overthrow the strongest reason, she remained without delirium, and within a year was reported to be entirely recovered. Shortly after the above-described occurrence she ceased to be my patient, but I have the statement of her sister that at no time since the catastrophe did she manifest a tendency to delusions materially different from that which she showed before it. This case also well illustrates the purely subjective nature of the emotional pain of melancholia.

As an example of simple melancholia running into terminal dementia may be cited the following case of Miss C——, whose alienation has now lasted seven years, and which ran the ordinary course. At the present time Miss C—— is silent and unsociable, preferring the solitude of her room, where, if allowed, she would sit by the hour, examining some article of dress, or biting at her finger-nails, occasionally uttering exclamations of disgust freely interlarded with profanity. She makes many odd motions and gestures, such as tossing her head, twitching her shoulder, or stamping with her foot. At the table she delights in handling the articles of food, and seems to be at a loss to know what to select. When eating she makes the most horrible faces, and watches every mouthful of food taken by the other patients, at times uttering grunts of disapproval. She is a great spy, and when she sees persons in close conversation she sneaks around and usually manages to catch more or less of what they are saying. In this way she manages to keep pretty well posted on what is going on about her. She is untidy in her dress and habits, and prefers to use the *pot de chambre* in her room rather than go to the closet, which is but a few steps away. She likes to wear her wrappers threadbare, and curses roundly when she is compelled to put on a new one. Her physical condition, always poor, improves somewhat, and her functions become more nearly normal as she falls deeper and deeper into dementia.

Treatment.—If physicians will keep in mind the pretty constant relation which exists between simple melancholia and disorders of the general health, they will have a very trustworthy guide to therapeutics. The correction of uterine displacements or the repair of a lacerated cervix, cure of a prostatorrhœa, or the dilatation of a stricture, is often attended with the most gratifying effect on the patient's sense of wellbeing. Again, someone has said that the sources of human felicity lie chiefly in the healthy stomach, and certain it is that the relief of chronic dyspepsia often lifts a patient out of despondency and gives him a new interest in life. Clouston says that fat and melancholia are natural enemies. In short, the physician will resort to every means which will increase the patient's strength and improve his physical condition, and to this end he will turn his attention first to the gastro-intestinal tract. Early treatment will be the most effective, alleviation becoming rapidly more and more difficult of accomplishment after the malady has existed for a year. Patients prone to this trouble should be informed and warned that any falling off in their bodily health is pretty certain to result in painful mental depression.

And there is the matter of suicide, the responsibility for which the friends of the victim usually try to lay at the physician's door. Here there is only one rule. As already stated, all persons suffering from simple melancholia, in the early stages of their disease, at least, should be regarded as suicidal; and the physician is false to his trust if he does not warn and instruct the friends accordingly.

And I do not feel justified in closing this paper without emphasizing the following facts: First, simple melancholia is a very common condition. Second, if treated early and properly it is a very curable one. Thirdly, it is out of this unfortunate class that suicide claims probably a majority of its victims.

THE ASSOCIATION OF TABES AND PARALYTIC DEMENTIA.[1]

Report of Five Cases.

By THEODORE DILLER, M.D.,

PITTSBURG.

VISITING PHYSICIAN TO ST. FRANCIS HOSPITAL.

Nearly all observers are now agreed that syphilis is the most important etiological factor in the production of both tabes and paralytic dementia. To say that syphilitic history is present in four-fifths of all cases of tabes and in two-thirds of all cases of paralytic dementia, would probably be a conservative statement.

It has been observed that tabetic symptoms develop in the course of paralytic dementia. On the other hand, general paresis may develop in the course of locomotor ataxia. Just how frequent the association of tabes and paresis is, cannot, with our present information, be determined. Mickle[2] takes exception to the statement of Sachs[3] that the development of general paresis after tabes is "frequent," holding (and to my mind, very properly) that we must distinguish sharply between true tabes and the mere ataxic or tabetiform symptoms which are common enough in general paralysis.[4]

These considerations and the fact that some of the cortical changes characteristic of paresis have, by Nageotte[5] and others, been found in those dying of tabes, have moved Fournier, Strumpell, and Jendrassik[6] to regard tabes and paralytic dementia as two different clinical manifestations of the same morbid process, whose seat in one case is in the cord and in the other in the brain. Then, according to this thought, it would be very natural to suppose for *a priori* reasons that in some instances the pathologic process which involves, first, the cord, would subsequently involve the brain, and *vice versa*. Whether or not this view be accepted, the conviction is growing that the association between these two affections is very close indeed. We need yet further light to show that they are only different manifestations of the same diseased process.

It would seem that a complication or association as important as this should receive mention in works on nervous diseases. Unfortunately this is not the case. Gowers, however, with his usual grasp of all aspects, complications, and association of nervous diseases, points out[7] that a "very important and frequent complication of tabes is general paralysis of the insane." He goes on to remark that tabes or paresis may complicate each other, and that the symptoms of one or the other affection may preponderate, and states his belief that the "correct expression of the facts is the coexistence of the two affections, and the dominance of the symptoms of the one or the other."

As a contribution to the study of this important question the clinical records of the following five cases are submitted:

Case I.—F. H——, policeman, aged fifty-eight, admitted to St. Francis Hospital, February 2, 1895. He was a very large, heavy man. Upon admission he was very noisy and excited, and slept poorly. In his conversation, which was rambling and rather incoherent, he expressed ideas of wealth and great power. Articulation, very slurring. There was a tremulousness of face muscles and a tremor of tongue and hands. Control over sphincters partially lost. His gait was very ataxic; knee-jerks absent. Pupils responded to neither

[1] Paper read by title at meeting of American Neurological Association, held in Boston, June 8, 1895. Account of Case V. has been added to the paper as originally prepared.

[6] Quoted by Mickle.

[7] Diseases of the Nervous System, vol. i., p. 417.

light nor accommodation. He died from exhaustion about a month later. No autopsy was allowed.

Case II.—J. M——, druggist, aged forty-three, admitted to St. Francis Hospital, September 30, 1894. At that time he presented the following symptoms: marked static and locomotor ataxia; entire absence of knee-jerks; Argyle-Robertson pupils. Mentally he was quiet, somewhat depressed, and disinclined to talk. He soon changed from this state and became very noisy, blusteringly talkative. He spoke of electricity a great deal, saying that he had devised a new method of generating it profitably, and expected to supply the entire city of Pittsburg with it. He declared that he was possessed of great wealth, owned many fine teams of horses, and that he was a man of very extraordinary and peculiar dignity. During this excited period he had much difficulty in articulation, his words being slurred and often indistinct. Tremor in tongue, face, and hands was noted.

Twice the patient improved a great deal as to his mental symptoms. At present (May, 1895) he entertains no delusion, is quiet, rational, although somewhat despondent, and some element of dementia is apparent.

The ataxia and other tabetic symptoms remain unchanged.

Case III.—J. J——, salesman, aged forty-four, widower, admitted to St. Francis Hospital, August, 1893, with the history that he had become rather suddenly insane four weeks previously, and that he had since grown constantly worse. Upon admission he was noisy, garrulous, and at times very loud and excited. He declared that he was possessed of enormous wealth, and frequently offered immense sums to attendants for trivial favors. His gait was extremely ataxic, so that he could with the greatest difficulty walk a short distance alone. Both knee-jerks absent. Pupils somewhat dilated, responsive to neither light nor accommodation. At times he complained of severe pains in his abdomen and thighs. Slurring articulation; face and hand tremor. It was thought that he might injure himself in his efforts to get about, so he was put in bed and kept there during the few months he was in the hospital. He grew feebler and much emaciated, and became careless and filthy in his habits. At times he was quiet, but not for long periods. The expansive delusions never left him. After four or five months he was removed to the City Farm, where he died a couple of months later.

Case IV.—H. E——, tailor, aged forty-two (seen in consultation with Dr. J. M. Douthett, March, 1893). In 1870 he contracted syphilis, for which he was treated and believed himself cured. Symptoms broke out in 1871 and again in 1881. For many years has been addicted to excessive use of liquor. He states that for sixteen years past he has been troubled at times with shooting pains in the lower limbs from the waist downward; has consulted a great many physicians for this, and they all said the pains were rheumatic. Before seen by me, Dr. Douthett had noted the symptoms of ataxia, Argyle-Robertson pupils, and loss of knee-jerks, and diagnosed the case as one of locomotor ataxia. For some months past his business habits had been loose and he had become careless in dress. He had a number of optimistic enterprises on hand. Following a debauch, he became loud and excited in manner and exhibited some delusions of grandeur. When I saw him the tabetic symptoms, as noted, were present. He was exceedingly talkative and revealed to me a number of business projects, which to him seemed to promise rich returns. He stated that he had every reason to be contented and hopeful, whereas his personal, domestic, and business conditions were such that an exactly contrary state of mind would have been most natural. A tremor of tongue and hands was noted. He was sent to an asylum.

Case V.—William L——, bookkeeper, aged fifty, admitted to St. Francis Hospital, June 4, 1895. Has been married eight years; no children. Six years ago contracted syphilis; had secondary eruption and mucous patches. A year and a half ago he showed some difficulty in walking, and this has been slowly increasing. Six months later mental symptoms were noted. He became dull, careless; showed defects of memory; speech became thick, slurring. All these symptoms were on the increase when he was admitted to the hospital.

Examination, July 6, 1895.—Gait ataxic: walks with feet wide apart; cannot stand with feet together when eyes are closed. The gait, however, is not a typical tabetic one, in that the high step and quick, jerky movements are absent. Pupils small; react very slightly to accommodation and not at all to light.

Mentally there is a marked degree of dementia. There is a fatuous sense of *bien-être*. Speech is thick, slurring. There is, especially at times when he becomes emotional, a tremulous condition of the facial muscles. No delusions of grandeur. His history before coming to the hospital is imperfect, and it is not known that he ever possessed any delusions of grandeur.

In all five of these cases the diagnosis of tabes seems quite clear, unless, perhaps, Case V. be excepted, and even here the diagnosis appears very probable.[1] They are not cases of paralytic dementia presenting tabetiform symptoms. For the symptoms of tabes in all cases except Case I. (in which this point cannot be determined, because of the meagre history) preceded the paretic symptoms. In Cases II. and III. the history does not state this point definitely, but it may fairly be inferred from the fact that the tabetic symptoms were so marked when treatment for mental symptoms was sought.

The two most important of the cardinal symptoms of tabes, viz., ataxia and loss of knee-jerks, were present in all five of these cases, except that (as previously noted) ataxia was not characteristic in Case V. The lightning pains were known to have been present in only two cases (III. and IV.). In one case (IV.) they were present for many years. This symptom may have been present in the other three cases, but the history does not record the fact, and the mental condition of these patients was such that they could not remember them.

The pupillary symptoms are noteworthy. In Cases I. and III. the pupils responded to neither light nor accommodation, and in the latter case they were dilated. In the remaining three cases they presented the Argyle-Robertson type of phenomena.

As to the symptoms of paresis, dementia, delusions of grandeur, tremor, and defective articulation they were present in all patients, excepting Case IV. (where speech was not defective), and Case V. (where delusions of grandeur were not noted). In view of the presence of these symptoms the diagnosis seems plain in all these cases.

In two cases (IV. and V.) there is a clear history of syphilis. It is not known whether or not any of the other three cases were syphilitic.

Westinghouse Building.

Travail and Travel.—A Boston daily is the authority for the statement that one of the companies that run lines of steamers on the great lakes announced that it would give a prize of $250 in gold for every baby born on one of its vessels this season; $500 for twins, and $1,000 for triplets. This was certainly encouraging, the prize for triplets being notably appreciative. They are worth the price, the writer said, and the money would start the parents off very handsomely under what would otherwise be unfavorable conditions. We have not heard that the birth-rate on the great lakes was higher than usual this summer.

[1] Since this was written the diagnosis of associated tabes and paresis seems plain.

INFLAMMATION OF THE UTERINE APPENDAGES (SALPINGITIS).[1]

By SOLOMON G. KAHN, M.D.,

LEADVILLE, COL.

LATE HOUSE PHYSICIAN AT ST. MARK'S HOSPITAL, NEW YORK CITY.

Every practitioner is aware of the fact that the present century is full of changes in the theories and practice of medicine. Perhaps in no branch of our science has more been done for the alleviation of human suffering than in that pertaining to diseases of women, and to the consideration of one of these I, for a moment, invite your attention.

As we are informed by Pozzi: "In the attempt to understand the connections between the uterus and the Fallopian tubes, it must be borne in mind that they have a common embryonal origin.

"At the end of the second month of intra-uterine life, Miller's ducts fuse inferiorly to form the uterus and the vagina, while they remain distinct above and constitute the tubes. The latter are, in reality, only the slender prolongation of the uterine cornua. There is an immediate continuity between their different coats, from which arises the possibility of an ascending salpingitis consecutive to an inveterate cystitis. The ovary connected to the tube by the tubo-ovarian ligament is in almost immediate contact with its pavilion, and may be infected by contiguity. These organs are also united by important vascular and lymphatic connections. I need scarcely remind you of anastomoses of the utero-ovarian arteries and veins with those of the uterus; still more important are the lymphatics. There is a remarkable lymphatic group occupying the space between the tube and the ligament of the ovary. Important relations, completing the already close anatomical connections, are thus established between the ovary and the tube. Thus there is, so to speak, no ovaritis without salpingitis, and no salpingitis without ovaritis; the inflammations of the appendages are then properly combined in the same description. Almost always the inflammation passes from the tube to the ovary directly by contact and by adhesion. But sometimes there is also observed a suppuration of the ovary without continuity with the inflammation of the tube. This fact can then be explained by the lymphatic relations. The vessels which come from the pavilion follow the external lateral ligament and empty into the large lymphatic plexus called the subovarian plexus. There is then no difficulty in comprehending that an abscess of the ovary may be observed. With relatively small lesions of the oviduct, the adhesions, which are rich in lymphatics, may serve to carry the inflammation. The lymphatic net-work which covers the surface of the ovary also communicates extensively with that of the peritoneum. If, then, the peritonitis, consecutive to inflammation of these organs, usually remains circumscribed, it is, without doubt, because an early stage of the process consists in a plastic obliteration, a sort of adhesive lymphatic thrombosis.

"Finally, the subperitoneal cellular tissue that exists in the wings of the tube and of the ovary, is in connection with that of the broad ligaments, which is itself continuous below on the pelvic floor, and on the sides with the lamellar tissue, folding in with the peritoneum and offering a special laxity in front of the bladder in the pseudo-cavity of Retzius. The knowledge of these peculiarities is indispensable for the explanation of the deep and the superficial propagation of the inflammation."

The importance of the subject and the frequency of the disease may be inferred from the fact that Winckel, out of five hundred autopsies made on women, found three hundred of them to have had salpingitis of a greater or less degree. There have been many classifications of salpingitis described. The one to which reference will be made in this paper is that formulated by Dr. H. J. Garrigues and given in his text-book on "Diseases of Women."

Different Forms.—It may be acute catarrhal or acute purulent, both of which are seated in the mucous membrane, and are therefore called endosalpingitis; or it may be chronic interstitial, which is also called pachysalpingitis, mural salpingitis, or parenchymatous salpingitis, and is located in the muscular coat. Salpingitis may be cystic, and, according to the character of the fluid contained in the dilated tube, it is called pyosalpinx, which is filled with pus; hydrosalpinx, which contains a watery fluid, and hæmatosalpinx, the contents of which are bloody. Perisalpingitis is the inflammation of the peritoneal covering of the tube, a condition which only occurs as part of a more extended pelvic peritonitis.

Profluent salpingitis is a variety characterized by the discharge of a watery fluid, pus, or blood from the tube through the uterus and vagina. When the fluid is watery the disease is also called hydrops tubæ profluens, or intermittent hydrocele of the ovary.

Under the name of salpingitis, isthmica nodosa has been described, a form of chronic salpingitis in which nodules can be felt at the corners of the uterus. In their interior is found the tubal canal, hyperplasia, and hypertrophy of the muscular elements of the wall, and sometimes cysts.

Pyosalpinx saccata is a variety of pyosalpinx in which the lumen of the tube is partitioned off into a series of pus-filled sacs, which partitions may subsequently become absorbed so as to form one cavity. Taking the etiology as base for a classification, salpingitis may be divided into infectious and non-infectious. The non-infectious is always catarrhal; the infectious is nearly always purulent, but may, in the beginning, or toward the end of the disease, be catarrhal.

The causes of salpingitis in many cases cover a multitude of sins and imprudences, either produced by the woman herself or someone else. Gonorrhœa and septic infection cause the greater number of cases. Abortions, which are complete or incomplete, causing many cases also, which sometimes do not manifest themselves for several years; endometritis, metritis, too frequent coition, exposure to cold just prior to, and during, menstruation, exanthematous diseases, syphilis, tuberculosis, and frequent douche of cold water. Last, but not least, any manipulations of the cervix or uterus without surgically clean hands or instruments. The symptoms are many and varied. When seen in its first stages the patient may only complain of a peculiar discomfort of the external genitals, urethra, and uterus, on one or both sides. Pain may be slight or severe; referred to the sacral and lumbar regions or down the thighs, also in the iliac fossa and epigastrium, exaggerated by undue exercise. Sometimes they have pain caused by the tumor pressing on the nerves in the pelvis. Pain more or less severe during defecation, which does not occur daily with these patients, who usually suffer from chronic constipation as an adjunct to their other troubles. Some only complain of pain during coition. Menstruation may be profuse and irregular, the pain becoming more severe at that period. Some of these symptoms may be, and are, frequently overlooked, and the patient treated for hysteria and dosed for months; the knowledge of the real trouble escaping the attention of the attending physician. Should a few drops of pus from the fimbriated end of the tube escape into the abdomen, thereby setting up a pelvic peritonitis, the cause of which might still escape the attention of the medical attendant, a vaginal examination ought not to be neglected.

As regards treatment, it is well for us to remember, in this connection, that every case of metritis in every instance, whether specific, septic, or non-septic, will,

[1] Read at a meeting of the Colorado State Medical Society, held June 20, 1895

sooner or later, extend to the tubes, causing salpingitis. Therefore, the most important treatment is prevention. If all cases were recognized before the tubes are involved, and properly treated, we would have very few cases of salpingitis. When a salpingitis is acute, the usual palliative measures of cold applications to the abdomen, with hot vaginal injections, absolute rest in bed, a fluid diet, and opium are employed. But it is the subacute and chronic cases which cause us the greatest anxiety and make confirmed invalids of our patients, which we wish to consider. It has become quite a fad to remove all diseased tubes, but a great many tubes can be saved by a palliative treatment, if properly carried out. Numerous cases may be seen, which were due to endometritis, cured by curetting the uterus and then treating the diseased tubes locally; and also where an eroded and enlarged cervix is found with salpingitis, a great advantage may be gained by treating with applications of a five-per-cent. solution of aluminum acetate. The best local treatment, perhaps, is to use ten per cent. ichthyol glycerine tampons in the vagina twice a week, at the same time employ hot vaginal injections twice a day. In chronic cases have them use a Priesnitz at night and remove it in the morning; also frequently paint the posterior vault of the vagina with iodine. Sometimes a better result will be obtained by confining the patient to her bed for a week or two, giving her hot vaginal injections three times a day, and introducing the ichthyol tampons every night. Electricity has been recommended, but it may be doubted if the value has been proven; also massage. If massage is to be used, it should only be in chronic cases, for the reason that if used where there is any inflammation it will aggravate it. If none of these measures cure or relieve the patient, then the question of removing the tubes may be considered. Laparotomy has always been the extreme measure employed. But recently the operation of vaginal hysterectomy has been advocated and substituted by Drs. Polk and Boldt, of New York, in cases where both appendages must be sacrificed, as ascertained by the history and examination.

The following report of two cases are selected from a number of similar ones, treated agreeably to the course laid down in this paper:

On August 7, 1894, Mrs. Emma S——, thirty years of age, applied to me for treatment; family history good; commenced menstruating at the age of thirteen years; always regular and free from trouble at those periods; pregnant three times, carrying her children to full term. In the month of May, 1892, she was delivered of a healthy child at full term. Her trouble dated from that time. Complained of pain, at period of menstruation, on left side and back; nausea at irregular intervals, accompanied with diarrhœa; constant feeling of lassitude, all of which incapacitated her from performing her household duties. On bimanual examination I found the left tube and ovary painful to touch, and enlarged to the size of a goose-egg; temperature of vagina elevated, with inflammation of entire pelvis. Discharged from treatment, October 8, 1894. Treatment consisted of the introduction of ichthyol tampons twice weekly, with a general tonic. Patient reports herself, May, 1895, entirely free from her former trouble, from date of discharge.

On February 27, 1895, Mrs. Kate T——, aged thirty-four years, came under my treatment. Menstruated at thirteen years of age; married when twenty-one; has three living children. In July, 1894, aborted at six weeks, from which date she has suffered from the following symptoms: Pain referred to left side; menstruated profusely at irregular periods; on bimanual examination found an enlarged left tube; speculum revealed an enlarged and eroded cervix. Treatment: Application of aluminum acetate to cervix, followed by introduction of ichthyol glycerine tampons. Patient discharged from further treatment April 30th, since which time she has been free from pain and irregular menstruation.

19–21 Union Block.

A METHOD OF EXPRESSING THE DEGREE OF ACIDITY OR ALKALINITY OF ORGANIC AND OTHER FLUIDS.

By J. B. NICHOLS, M.D.,

clinical assistant, united states soldiers' home, washington, d.c.

In laboratory work the necessity frequently arises of estimating the degree of acidity or alkalinity of organic and other fluids, as in the examination of stomach contents. Various methods are in use for expressing the acidity or alkalinity, as in the case of urine by the terms of an equivalent solution of oxalic acid, and in that of stomach contents by the number of cubic centimetres of a decinormal alkaline solution required to neutralize 100 c.c. These methods are more or less arbitrary and empirical. It would seem desirable that a uniform and rational system should be adopted applicable to all fluids to express the results of volumetric acidimetry and alkalimetry. It is the purpose of this note to present a scheme which I use in my own work with urine and gastric fluid, and which seems admirably suitable for its purpose.

The natural standard is the normal solution. This is the standard adopted in the system here presented, with its acidity or alkalinity, as the case may be, fixed at the number 1. All other degrees of acidity and alkalinity are expressed by the numbers (decimals or integers) indicating their strengths, relative to the normal solution as 1. This standard may, if deemed advisable, be expressed by the letter N. Thus, an acidity expressed as .022 (or .022 N) would mean that the acidity of the fluid is twenty-two thousandths that of a normal acid solution; .001 N would represent a strength of one-thousandth of a normal solution; a fluid of which 10 c.c. would be neutralized by 4.5 c.c. of decinormal acid would have an alkalinity of .045 N; 2 N would represent a strength double normal; decinormal and seminormal solutions would be represented by .1 N and .5 N respectively. The latter are frequently expressed in fractional form, $\frac{N}{10}$, $\frac{N}{2}$. The system here suggested contemplates an extension of this method of notation to acid and alkaline fluids of all strengths, only the decimal form is more generally convenient than the fractional.

It might at times be also found convenient, as in tabular matter, to denote acidity and alkalinity by the signs + and — respectively. This method of notation appears to me to be the best for its purpose. It is of universal applicability to all acid and alkaline fluids, and expresses results in a uniform manner. As all normal solutions are of equivalent strength, this method affords a means of direct comparison not only between fluids of the same reaction, but also between acids and alkalies. It is simple, rational, and natural, the normal method as it were, and completely corresponds with the system of normal solutions.

The acidity or alkalinity so expressed is directly proportional to the percentages by weight of acid or alkaline substances present, which may be readily computed by means of normal factors. Thus, a strength of .001 N corresponds to .003637 per cent. by weight of hydrochloric acid, .004489 of absolute oxalic acid, .003996 of sodium hydrate, .00219 of carbonic oxide, etc., from which the weight percentages can be readily determined.

In any titration, where two fluids are mixed to exact neutralization, the number of cubic centimetres of the one fluid used, multiplied by its acidity, is equal to the number of cubic centimetres of the other fluid multiplied by its alkalinity. The number expressing the acidity or alkalinity can therefore be easily calculated,

in any titration, by the following rule: Multiply the number of cubic centimetres of the test solution used in titration by its alkalinity or acidity and divide the product by the number of cubic centimetres of the fluid being tested which is employed; the quotient expresses the acidity or alkalinity of the latter. Thus, if it requires 6.8 cc. of decinormal sodium hydrate solution to neutralize 8 cc. of stomach contents, the acidity of the latter equals $6.8 \times .1 \div 8 = .085$.

PALLIATIVE TREATMENT OF HAY FEVER.

By FREDERICK G. SMITH, M.D.,

SOMERVILLE, MASS.

THE prevalence of hay fever, especially at certain times in the year, is of such frequent occurrence, and symptoms so characteristic, that its recognition is not difficult even by the laity. So periodically regular is its appearance that the practitioner is almost sure to meet it during the months of August and September. Indeed, many patients can foretell its onset with precision even to an hour.

In endeavoring to treat a disease on a rational basis, the regular physician always strives to remove the cause, and it is a well-known fact that diseases in which the cause is imperfectly understood are the most unsatisfactory to treat. It is not intended here to discuss the etiology of hay fever, but while this curious disease has been very closely studied for many years and brilliant theories and ideas advanced relative to its cause, there are none that are at present universally accepted. Confronted, therefore, by these facts, the hope of obtaining a specific for its cure must necessarily be shaded until further investigation has been made. Where the cautery can be used, it undoubtedly produces the best results if thoroughly applied. This is a disagreeable procedure, requiring sometimes several sittings, and will not, for various reasons, be used by many physicians.

A large majority that apply for treatment to the general practitioner are not possessed with the means to take a sea-voyage or to spend several months in the mountains, so we must resort to means more within the reach of all. Referring, then, to the palliative treatment, local applications are to be recommended. Sprays of various sorts produce only a transitory effect, besides not being convenient. Cotton has been used in the nose with a view of preventing the irritating substance, whatever it may be, from gaining access to the hyperæsthetic membrane, but most people do not like the sensation, and the cosmetic effect is not wholly attractive. Ointments produce a twofold effect, viz., combined with anæsthetics they diminish hyperæsthesia, and shield the nerve-terminals from irritation. The following combination I have found very effectual, and I have yet to see a case where it did not give almost instant relief.

℞ Mentholis ..... grs. xx.
Olei amyg. dulcis ..... ʒ ij.
Acidi carbolici ..... ♏x.
Cocain hydrochlor. ..... grs. vj.
Ung. zinci oxidi ..... ʒ ss.

Sig.: Apply thoroughly to the nostrils on cotton attached to a tooth-pick.

It will at once be seen that cocaine is the chief drug to be relied upon, but I do not think it is the only one, as I have used it in other ways with much less satisfaction. It is the combination as a whole that I think worthy of notice, and while empiricism ought generally to be discouraged, I think in the disease under consideration it seems justifiable. There are adjuncts that are valuable in these cases depending upon the general condition of the system. Out-door exercise, Blaud's pill in anæmia, and arsenic, strychnine, and phosphorus, as indicated, are too well known to warrant comment.

Progress of Medical Science.

Intestinal Obstruction in Children.—Dr. Monti, after discussing the causes and general symptoms of intestinal obstruction in children and accepting in the main the views of Leichtenstern, gives the following points as those which are of value in forming an opinion as to the site of the obstruction (*British Medical Journal*): 1. In the lower part of the colon the first symptom of acute obstruction is painful colic, and the region of the abdomen in which the colic is first felt may afford some indication of the part of the colon obstructed. Vomiting does not occur until the colic has lasted for some hours or days; it is at first bile-stained, then becomes foul, and finally feculent. Collapse sets in late: gaseous distention of the intestine begins in the colon, and at first it may be possible to make out that it is limited to the region occupied by the colon (flanks and epigastrium), but later the ileum also becomes distended, and the tympanites may reach a very high degree. In incomplete obstruction the symptoms are the same, but develop more slowly. Action of the bowels may occur, and be attended by temporary relief, especially of the tympanites. If the rectum be incompletely obstructed, constipation alternates with attacks of painful tenesmus, followed by the passage of small scybala. Circular constriction of the rectum causes the motions to be of small calibre. 2. Acute obstruction in the lower part of the ileum is attended with frequent attacks of painful colic, starting in the ileo-cæcal region. Each paroxysm of colic induces an attack of vomiting, the vomited matter being at first the contents of the stomach, but later fecal. Collapse sets in early. The distention of the abdomen is most marked at first in the umbilical and hypogastric regions, but in time becomes general; it is not notably diminished by vomiting. At first several fecal stools may be passed, but after a few days there is complete constipation. The quantity of urine is diminished after the first few hours or days, and there may eventually be suppression. When the obstruction is incomplete the colic may be as severe, and the movements of the coils of intestines perceptible. The degree of distention may vary greatly in a very short time, and this independently of the passage of a stool. The constipation, after lasting some days, may be succeeded by copious, foul diarrhœa. 3. Acute obstruction in the duodenum or jejunum causes severe colicky pain, starting about the umbilicus and radiating toward the stomach. Vomiting comes on early, and is violent; the vomited matter is at first bile-stained, later it becomes foul smelling. Gaseous distention is slight, and is limited to the epigastrium. It may be very much diminished by vomiting, but collects again. The bowels may at first act spontaneously or after enema, but eventually there is complete constipation. Suppression of urine is established early. When the obstruction is not complete, the symptoms are similar but less severe. The colic is painful, and the vomiting, either in relation with the colic, or independently, very frequent. The quantity of urine is diminished. There is no distention of the abdomen, and diarrhœa alternates with constipation. Monti considers that if a case is seen early much may be learned as to the probable seat of the obstruction by observing the way in which the tympanites develops.

The Library of the Surgeon-General's Office of the United States Army now contains 116,847 volumes and 191,598 pamphlets.

Every Fatal Case of Typhoid, says Mr. Ernest Hart, is, in fact, a violent death, an example of water poisoning, and should be the subject of sanitary inquest.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 43, 45, & 47 East Tenth Street.

New York, October 5, 1895.

SUNDAY LIQUOR-SELLING FROM A DOCTOR'S STANDPOINT.

THE discussion of the excise question, of local option and of Sunday liquor-selling, which now interests so many, has a medical and scientific side which should not be entirely neglected. It is very proper that those people who are anxious to provide (or deny) opportunities for drinking every day in the week, should, in a measure, consider not only the question of "personal liberty" and the "poor man's rights," but also the question whether the habit of drinking liquor on any day may not be injurious to the body of citizens as a whole. Our readers will remember that not many years ago, the question of the danger or lack of danger from the use of alcoholic drinks, was very widely agitated among medical men, and that many learned opinions were given, very largely by eminent English physicians, as to the safety, or otherwise, of the habit of moderate drinking. The conclusions, at that time, seemed to be, from all the facts and opinions that could be gathered, that a large number of persons could drink temperately for years without really impairing their health or shortening their lives. Since that time a good deal more evidence, as to the action of alcohol upon the human body, has been collected, not by hysterical prohibitionists, but gathered from the laboratory, the autopsy-room, and the bedside. One series of facts, opening up a decidedly new field, has been obtained through the works of the experimental psychologists. Through the efforts of some of these gentlemen, and we may mention particularly work done at the Heidelberg University, it seems to be established that alcohol has an effect in dulling certain mental processes, such, for example, as learning by rote, simple arithmetical calculations, and the simpler association of ideas. Another series of facts which tend to show the evident effects of alcohol, is that which have been collected by students of heredity, particularly the relation of heredity to degeneration in families. The French alienists, in particular, have shown that one of the most prominent of the factors in leading to development of mental and physical degeneration, is the use of alcohol, and it is further urged by these investigators that alcohol has more than an individual or family effect, that it produces serious deterioration of the human race. Of course, the effects thus claimed are all due to the abuse and excess of alcohol. Whether a further and more careful investigation would show that a moderate use of alcohol leads, eventually, to somewhat similar results, we cannot say. As regards the evidence against alcohol, furnished by clinicians and pathologists, there has really been nothing particularly new added in late years. But if one take an unbiassed survey of the position of medical knowledge and of medical men toward alcohol, and compare it with that held by them fifteen years ago, we feel sure that he will see that the feeling against the use of it is much stronger. This is because there has been a gradual accumulation of facts carefully ascertained and thoroughly proven, demonstrating the ill effects of the drug.

It is for the reason that the position of medical men regarding the use of alcohol has been always conservative and never fanatical, that the present slight shifting of the front deserves the attention of our law-makers and of all those citizens who are interested in good government and in the social problems of the day.

TUBERCULOSIS AND THE LIBRARY.

THE statement has passed current that a librarian of the city of Omaha, Neb., recently died of tuberculosis contracted from books which had been infected by consumptive patients. This report has naturally renewed the discussion regarding the danger of infection by means of public libraries. There are many physicians who are aware of cases in which some of the more actively contagious and portable diseases have been communicated by means of books, though not, perhaps, by the books of a public library. We recall, for example, instances in which scarlet fever was apparently communicated in this way. Practical experience, however, in the large cities, where there are well-patronized public libraries, seems to show that little danger is to be apprehended from this source. This is particularly the case in cities that are supplied with proper health boards and with modern sanitary methods. The danger, so far as it exists, could only apply to a few diseases of the more active kind, like scarlet fever and perhaps small-pox. Regarding this latter disease, *The Evening Post* quotes the remarks of a Boston physician, who says that he has never known an instance where there was any grounds for believing that contagious diseases were carried by books in circulation in the public library. In the year 1872 a severe epidemic of small-pox prevailed in Boston, and the physician in question saw every patient and traced, where possible, the history. In no instance did he connect the infection with the use of books. As the circulation of this library is more than two million volumes a year, this evidence is very convincing. We understand, also, that the American Library Association has twice investigated the subject of books and contagion, and in no instance was it able to trace the spread of disease to the circulation of library books. The American Library Association might, perhaps, be considered a body not entirely without bias in favor of circulating books, but its investigations were apparently thorough.

Despite all this, it would be wise to exercise a sanitary supervisi. over the circulation of books. Their

disinfection, when they have gone into neighborhoods that are at all suspicious, would be extremely easy, and the co-operation of a public library with the sanitary officers of the city might result in good to both parties and benefit to the public.

DOCTORS' WIVES AND PROFESSIONAL CONFIDENCES.

A London journal lectures medical men on their "leakiness" as regards the personal affairs of their patients. The editor says (we quote from the *British Medical Journal*) that the great sinner is the country doctor. It is, however, adds the *Journal*, only a matter of size. "Let the victim be but big enough, and urbans can babble as incontinently as any pagan of them all." The *Journal* is ungallant enough to hint that the error often begins by the doctor telling his wife. The partner of his bosom too often makes it a test of the loyalty of her husband that he tells her everything. "It is an old saying that a secret can be kept by three men if two of them are dead, but a woman conceals—what she does not know. A wise man will make it a rule never to speak to his wife of professional matters, never even to tell her the names of those who consult him."

A man may be wise enough to make such a rule, but will he be strong enough to keep it? Experience seems to indicate that he will not. The doctor is human and feels the need of a confidant; the wife is very human and likes nothing so much as domestic details.

We must deplore the "leakiness" of which the profession is accused. It is wrong; but there are imperfections in our social fabric which must exist for a long time—until, for example, woman ceases to be curious and man—to be her slave.

HOSPITAL CORPS AND THE STATE MILITIA.

The recent meeting in this city of the medical officers of the National Guard and Naval Militia of the State of New York, for the organizing of a trained hospital corps, is of great moment to everyone interested in the welfare and efficiency of our citizen soldiery. The experience in the late riots has so abundantly proved the prospective necessity of such a measure that there appears to be no reasonable doubt that the legislative assistance to that end which will be sought, will be granted accordingly. It will be a matter of surprise to many to learn that the provisions for the care of the sick and wounded have been for the most part made through voluntary contributions of the regiments themselves. In fact, it would appear that the only way in which proper instruments and appliances could be obtainable was by the private contributions of the surgeons themselves. Now that these facts are known, there will be no difficulty, we imagine, in obtaining from the State a sufficient appropriation to cover the actual and pressing necessities of the case. The militia of this State have shown their valor and efficiency in so many ways that their necessity as a State organization, liable for the most trying duties at the shortest notice, can no longer be questioned. It is then of the utmost importance that these self-sacrificing citizens, ever willing to do and dare in all emergencies, should be properly cared for. In the recent Brooklyn riot, this was made strikingly manifest. It was on that occasion due almost solely to the great efficiency of the medical staffs of the different regiments, that much real suffering and sickness were reduced to the minimum.

The organization of a distinct hospital corps becomes one of the necessities of the situation. Ample experience in the inefficiency of the prevalent system of special and chance details, has abundantly demonstrated this, and the medical staff, always alive to the best interests of the service, are becomingly timely and properly earnest in the advocacy of such a beneficent and useful measure.

POLICE ATTENTION TO ALLEGED TRIVIAL ACCIDENTS.

An effort is being made by the several hospitals, through a representation of the surgeons of these institutions, to relieve the ambulance service of those trivial cases, which might be treated by the police surgeons at their respective police stations. This would appear to be eminently proper on general principles, but there are so many difficulties in the way of making such service practically effective, that it is well to consider them before taking definite action. While it is very properly argued that a police surgeon of experience is better qualified to make a diagnosis as to the real gravity of an injury in obscure cases, than is the ordinary ambulance surgeon, such chances of neglect are more than overbalanced by the loss of time in the many cases requiring the prompt assistance which the police surgeon is confessedly unable to give. The ambulance system, as it is, is well distributed over the different districts, and hospitals vie with each other in their prompt attention to accidents. Not a few of the ambulance surgeons, in their zeal to get first to the case, are so thoroughly imbued with the spirit of generous rivalry that they always dodge the penalty of the "hindermost."

There does not appear to be any unwillingness on the part of the majority of the hospitals of responding "early and often" to all summons for relief. So far, then, the system can hardly be improved by any intermediate provision of expediency. More than this, however, would be the difficulty of deciding what were and what were not trivial cases. As the responsibility of so doing would mostly rest upon the policeman who first saw the case, rather than upon the police surgeon who might or might not be within reach at a critical moment, it is easy to see that the ambulances would have and should have the first choice.

Small-pox in London.—The English journals state that the outbreak of small-pox in London goes on increasing, despite the energetic measures taken by the health authorities.

Society Reports.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, September 23, 1895.

EGBERT H. GRANDIN, M.D., PRESIDENT, IN THE CHAIR.

Nomination of Officers, Censors, and Delegates.—For *President*, E. H. Grandin (declined), E. D. Fisher, Richard Van Santvoord; *First Vice-President*, Wendell C. Phillips, Frederick Peterson; *Second Vice-President*, J. Henry Fruitnight; *Secretary*, Charles H. Avery; *Assistant Secretary*, W. E. Bullard; *Treasurer*, John S. Warren; *Censors* (five to be elected), B. F. Curtis, Simon Baruch, Frederick M. Warner, A. M. Jacobus, E. H. Grandin, Seneca D. Powell, Frank Van Fleet, C. L. Gibson. About forty members were nominated as delegates to the State Medical Society, thirty-five to be elected.

The Importance of Asepsis in the Practice of Obstetrics.—DR. ADRIAN Y. REID, in a paper with this title, compared the methods and results of aseptic and antiseptic midwifery as practised in four city institutions with the same in the private practice of four physicians. The institutions included the Sloane Maternity, the City Maternity on Blackwell's Island, and the Lying-in Hospital for the Instruction of Medical Students at Seventeenth Street and Second Avenue. In the first named there had been but three deaths out of over four thousand cases, and in these three infection had taken place before admission. There had been no deaths in the last thousand cases confined at the City Maternity. The mortality-rate in the several institutions named, under present aseptic and antiseptic methods, was about one-eighth of one per cent., while that in the practice of the four physicians quoted was about one-fifth of one per cent. in a total of nearly one thousand confinements. Dr. John Woodman had had no deaths from sepsis in his last one hundred and fifty cases; Dr. Reid but one in his last four hundred and fifty-eight cases. The chief difference in the methods of aseptic and antiseptic practice in the institutions and in the hands of the private practitioner, was the omission by the latter of the vaginal douche before and after labor. Whenever possible, Dr. Reid insisted on cleanliness of clothing, bed-linen, towels, and napkins, washing of the external genitals with soap and water and some antiseptic, cleansing and disinfection of hands and instruments. The physician seldom arrived before the woman was in labor, and the surroundings were not such as to enable him to give a vaginal douche without liability of defeating the purpose for which it was intended, disinfection and asepsis. Nor was it practical to shave the pubes as was done in hospitals. He would irrigate the vagina subsequent to labor only in case of rents, and the uterus only after introduction of the hand, using then a 1 to 10,000 bichloride solution. If no complication arose, the patient was allowed to get up on the ninth or tenth day. While he did not object to the details of hospital asepsis being attempted in private practice, yet he did not think all of them necessary.

Antiseptic Midwifery Dates from 1883.—DR. H. J. GARRIGUES said October 1, 1883, marked a new era in strict antisepsis in the United States, the date when he changed the prevailing treatment in the New York Maternity. Just before he introduced antiseptic methods, the mortality had been about five per cent. During the last month it had been at the rate of twenty per cent.; the four months after introducing antiseptic methods no deaths occurred. He said he did not agree with Dr. Reid when he spoke of the fallibility of human effort in aseptic midwifery, for there were few things in which we had obtained such splendid results.

Sepsis Due to the Physician.—DR. R. A. MURRAY called attention to the fact that the worst cases of midwifery occurred usually in maternity hospitals, yet these now gave a smaller mortality-rate than was seen in private practice. The reason was that in private practice physicians did not do what they ought to secure asepsis. He believed that asepsis, in nine cases out of ten, was conveyed by the doctor. When the physician kept himself and his hands clean, he did not have sepsis, no matter what the surroundings of the patient. The chief thing to do was to clean our hands and not to touch anything before making the examination. The genitals should be cleansed with soap and water, but the vaginal douche was not necessary. He used carbolic acid or creosote for the hands; kept the bed as clean as possible, and especially had antiseptic napkins for use immediately after expulsion of the child. The nurse must not examine the patient. He had yet to see his first case of sepsis in his own private practice.

Aseptic Midwifery Less Formidable than it Looks.—DR. GEORGE W. JARMAN said the mention of the many antiseptics and antiseptic procedures enumerated in the paper might lead one to suppose that to carry out antiseptic midwifery was very difficult. But there was no physician who could not carry with him everything which was necessary in order to secure asepsis. One or two antiseptics were sufficient, and these, with soap and water and clean cloths, would secure asepsis. We should encourage aseptic and antiseptic practice. It was not sufficient that the patient recovered after labor; she should be left well, and not suffering with an endometritis, crippled tubes, etc., as so often happened.

DR. E. A. TUCKER said that on little inquiry one still learned of many women dying of septicæmia after childbirth, although fewer than formerly. This showed the necessity for a more general application of antisepsis and asepsis as practiced in maternities where the death-rate had been reduced to a very low percentage. Regarding the uterine douche, this was not necessary even after the introduction of the hand, provided the hand had been quite clean; it certainly was not necessary after version, since here the hand did not touch the uterus. He would not advise the uterine douche unless a foul fœtus had been expelled, or some such indication were present. Shaving the pubic hair could be done in a hospital, but it was not necessary in private practice. He was glad to hear the view expressed by a private practitioner that milk fever was septic. It was not necessarily so, but usually it was. Asepsis could be carried out in private practice as well as in hospitals, being essentially the same but not quite so elaborate.

DR. THOMAS DARLINGTON said that in country or sparsely settled districts he frequently found none of the conditions permitting of antisepsis as practised in the maternities. Sometimes there was an absence of soap, of boiled water, or water of any kind. He had confined nearly one thousand women, and had lost none from any cause. Whenever there was sepsis, it came from the physician, not from the patient. He carried bichloride tablets, and cleansed and disinfected his hands. He thought the vaginal secretions helped the passage of the head, and that the douche retarded it.

DR. ROSENBERG thought there was danger of infecting the woman by giving the vaginal douche. He thought the secret of puerperal infection was easily understood after one came to realize that the womb was absolutely aseptic, and that manipulations and douches were both unnecessary and harmful. Simply clean the hands before making examination; or better, do not examine at all.

DR. REID, in some concluding remarks, wished to

impress the fact that accoucheurs were not opposed to gynecologists and surgeons; all stood together in their aim to secure asepsis and aseptic results. While he believed it was not possible to carry out aseptic details in private practice to the extent that it could be done in hospitals, yet we should try and do as well as circumstances would permit.

An Appeal from a Decision of the Comitia Minora.—Dr. Frank Van Fleet read a printed statement containing an appeal from a decision of the Comitia Minora. A suit has been brought against him for damages to the extent of forty thousand dollars for his remarks before the Society when he had asked to have an advertisement expunged from the medical directory relating to eye-strain and the fitting of glasses by an optician not a physician. He thought the right of free speech and scientific discussion in medical meetings was involved, and that the Society should interest itself in the suit.

The President explained that the Comitia Minora had not thought it right to involve the Society in the defence of a suit for damages which was based in part on the remarks of a member regarding a certain case of which that member alone had any knowledge.

Dr. H. D. Noyes made some remarks upon a resolution offered by Dr. J. B. Emerson, saying that he felt very warmly upon this subject because he believed the right of free scientific discussion was involved. Much was exacted of physicians before they were permitted to practise medicine, yet in the medical directory published under the auspices of the Society was the advertisement of one not a physician presuming to advise physicians in the matter of fitting glasses for the relief of eye-strain, etc.

Dr. Emerson's resolution was adopted, appointing a committee of five—the President, and Drs. R. H. Derby, J. D. Bryant, D. B. St. John Roosa, and H. D. Noyes—to act with the Comitia Minora in the consideration of the matter.

Clinical Department.

A LONG SURVIVAL OF INJURY TO THE SPINAL CORD IN THE CERVICAL REGION.[1]

By JAMES L. KENT, M.D.,

BERTHA, VA.

In presenting this paper I do not aspire to teach you anything new, but to interest you in a case which is almost unique.

On July 22, 1893, a healthy miner, aged twenty-three, got into a drunken fight with several others, who struck him over the head with steel knuckles, caught him by his feet, and rammed his head against the ground until he was supposed to be dead. He was carried home unconscious, and his relatives, presuming that he was only intoxicated, paid no special attention to him, until he failed to get up next morning. Then I was summoned and found him in a very drowsy condition, from which he could with difficulty be sufficiently aroused to answer questions. There were several cuts over the left eye and a small scalp wound near the posterior superior angle of the left parietal bone. His face and hair were covered with dust. His face was markedly flushed, there was a slight elevation of temperature, very difficult diaphragmatic respiration, retention of urine, and absolute sensory and motor paralysis of the entire body below the second ribs. He could flex, but could not extend the forearms; could flex the fingers slightly, but could not extend them. I could not discover the slightest deformity of the vertebral column, but the patient suffered intensely if his head was moved laterally or lowered to the same plane as his shoulders. At 9 P.M. the same day his intellect had become much clearer, and he said that he did not remember anything that had happened since the previous evening, before he was injured. At this time his physical condition was much worse; pulse 138, full and bounding; respirations 35, and very labored; temperature 103° F.; suffering very great pain in the back of his neck and over the scapulæ, with continued retention of urine and constipation.

From this time on flexion of the upper extremities became weaker gradually, sensation in the fingers was soon lost, emaciation was rapid, and, in spite of early antiseptic precautions, cystitis developed at the end of the first week. Then came overflow of urine and fecal incontinence. There was occasional vomiting, but never any dysphagia. On the eighth or ninth day bedsores appeared over the sacrum and necrosis soon became so deep as to expose the sacral nerves. There was at no time that sensation of a band or constriction about the body, a symptom so often complained of in cases of spinal injury. There was nearly always a sensation of heat, but there was never any special elevation of temperature after the third day. The difficulty of breathing was greatly increased when the patient was placed on either side, or when his bowels became distended with gas. With the exception of a few days, when the diaphragm and serratus-magnus muscle seemed ready to rebel against doing the work of all the muscles of respiration, he breathed fairly comfortably, but dyspnœa came on oftener toward the end, showing that degeneration was approaching the origin of the phrenic nerves. (I could relieve the dyspnœa very much by four $\frac{1}{60}$ grain doses of strychnine sulphate, given every two hours until relief was obtained.) His consciousness remained clear until 8 P.M., September 7th, when he became unconscious and died one-half hour later, forty-seven days after the injury.

On September 9th, assisted by Dr. E. M. Wilkinson, of Patterson, Va., I opened the spinal canal and found the cord normal, except for a space of about one inch beginning opposite the articulation of the body of the sixth on that of the seventh cervical vertebra, and extending upward to near the origin of the sixth cervical nerves. For this distance the membranes of the cord were not broken and showed only slight signs of an old inflammation, but the substance of the cord was of the consistence of thick cream and exuded from the roots of the nerves as they were severed, leaving nothing but the connective tissue and membranes, which formed a thin flabby connection for the two ends of the cord. The vertical laminæ and spinous processes were intact, and the only sign of violence to the spinal column was the ruptured posterior common ligament between the sixth an seventh cervical vertebræ.

I could not remove the bodies for examination, as the autopsy was held under protest, and I had promised not to mutilate the corpse more than was absolutely necessary to ascertain the cause of death, but these were in normal relation, so that there must have been a displacement to tear the ligament with spontaneous reposition.

From the evidences at the time of injury and post mortem we concluded that the weight of the body was thrown on the forehead in such a way as to lift the sixth vertebra up and slide it back over the seventh, as there were dirty cuts on the forehead and nose, and the posterior common ligament was torn through while the ligamentum nuchæ was intact.

The violent displacement would bruise and constrict the cord sufficiently to cause its death at this point.

I regret that I cannot show microscopic sections of this cord, but it did not harden satisfactorily after ten months' immersion in Muller's fluid.

Ashhurst says that two-thirds of the cases of injury of the cord in this region die in the first week; this one lived nearly seven weeks.

[1] Read before the Medical Society of Virginia, during its twenty-sixth annual session, September 5, 1895.

A peculiar coincidence connected with this case was that his nurse had sustained a fracture of the spinal column in the lumbar region twelve years before, and recovered so that his only trouble was incontinence of urine and a slight muscular weakness of back.

There was an interesting paper on this subject, by Dr. Thomas H. Manley, in the MEDICAL RECORD of October 28, 1893.

GUNSHOT WOUND OF ABDOMEN.

By WILLIAM H. SIMMONS, M.D.,

BANGOR, ME.

THE following case is reported to show what good results may follow immediate operation under favorable circumstances:

Michael M——, aged fifteen, was shot with a 22-calibre rifle, April 27, 1895. Some three hours after the accident he was seen by me at the Bangor General Hospital, and at once operated upon with assistance of other members of the hospital staff. The bullet had entered about an inch above and to the left of the navel, and on the abdomen being opened was found to have passed through the edge of the left lobe of the liver and then through the stomach. Bleeding was going on from a vein near the greater curvature, and there were clots in the abdominal cavity. These were removed, the bleeding point tied, the wounds in the stomach occluded with Lembert suture, the intestines withdrawn and thoroughly searched for other punctures, finding none. The wound was sutured in layers, the boy put to bed, and discharged well May 16th. Convalescence was quite uneventful, no rise in temperature occurring.

TARTAR EMETIC IN TEDIOUS LABOR.

By JOHN T. DE MUND, M.D.,

RINGWOOD, N. J.

THE progressive period in which we live necessitates speedy and safe medicament. As chance has no law, I avail myself of clinical observation founded on facts. In a pretty large obstetrical practice of over thirty years, alone and in counsel, I have found that in the majority of confinement cases the rigid os and equally rigid perineum yield readily under the proper administration of tartar emetic, with no unpleasant effect upon the child in utero and none to the mother.

Tartar emetic is positively oxytocic, a something long looked for. It almost usurps the place of forceps—is a great aid to them when necessary; it casts into oblivion dilators—instruments of torture: and the inhalation of chloroform or ether may also be numbered with the things of the past.

The emptied bladder, the washed-out rectum, are two cardinal points in delivery; and third, the emptied stomach enables a certain stage of labor to progress rapidly, as well as favorably.

I will cite but one case among many. Mrs. ——, fourth delivery. Rigid os, strong, lancinating pains. I spent most of the night with the patient, who apparently made no progress. I then dissolved ten grains of tartar emetic in one-half tumbler of water and requested nurse to give two teaspoonfuls every ten or fifteen minutes till free emesis ensued. Perfect relaxation followed shortly, the expulsive effort was intensified, and the child, a bouncing boy, was quickly in the world. This was a fair case for forceps, chloroform, etc., "as we used to do."

It seems passing strange to the writer that so simple a remedy should have lain dormant till the present. My preceptor, the late Dr. John L. Atlee, of Lancaster, Pa., was the first operator in the world to remove both ovaries successfully. He was a good obstetrician, which I can vouch for, and yet at that time we little thought of this simple method of delivering a woman.

Briefly, if all obstetricians will study this one simple remedy and act accordingly, they will not labor in vain.

A CASE OF CARDIOCENTESIS.

By G. G. COTTAM, M.D.,

ROCK RAPIDS, IA.

I PRESENT this brief report of a most peculiar case, in view of the general interest now revived in cardiocentesis as a therapeutic possiblity, though the indefinite history, complex diagnosis, and irrational results do not warrant me in offering it as a substantial contribution to our knowledge of the subject.

Hans L——, aged fifty, Norwegian, came under my care in February, giving a history of rheumatic antecedents, and now supposedly suffering from asthma. His account of himself was devoid of any details of practical value.

Examination showed him to be affected with chronic bronchitis and mitral regurgitation, though no secondary effects of the latter had yet appeared. The possibility of pulmonary tuberculosis in an incipient stage was entertained.

He was then placed on general tonic and symptomatic treatment, with iodide of potassium on general principles. The symptoms continued without much change until June, when, compensation failing, it was found necessary to supplement the treatment with strophanthus, diuretics, and occasional hydrogogue purgatives. Digitalis did not act well.

The man's condition did not improve. Dilatation of the right heart set in, and his breathing became much oppressed, orthopnœa being pronounced and constant. The pulse at this time varied from 114 to 124, and was weak and compressible. The feet were œdematous, and there was a small peritoneal effusion.

The extreme symptoms evidently came from the distended right heart, and with the view of overcoming them temporarily, the feasibility of cardiocentesis was considered. This was put into execution a week later, the man's precarious state demanding that something radical be done to avert a fatal issue. Accordingly, I made an aseptic incision into the sixth interspace one inch from the sternum and inserted a long, slender trocar. By percussion this point had been determined on previously as the most favorable for approaching the right ventricle. The movement of the heart was distinctly felt as the point of the instrument entered the organ, the motion being somewhat of a "tugging" character. Then followed a continuous stream of blood, and I was puzzled to account for the color, a bright scarlet. The trocar was withdrawn after four ounces of blood had passed through it. During the procedure the man made no complaint, save of the sharp, pricking sensation caused by the entrance of the trocar through the chest-wall. He conversed without effort, and afterward rested quietly, though with but slight immediate relief from the dyspnœa. Five days later, however, he was breathing easily, though coughing constantly and expectorating profusely. His appetite, at no time good, failed almost entirely, and he became greatly emaciated. He was evidently now well advanced in pulmonary tuberculosis, and six weeks after the operation died of exhaustion.

A partial necropsy was performed ten hours after death. Both lungs were full of tubercular deposits. The heart had stopped in diastole. Removing the organ *in toto*, the cicatrix following the puncture was plainly made out and the course of the instrument traced, to my great surprise, through the wall of and into the cavity of the left ventricle. The mitral diag-

nosis was verified also, but nothing else of note developed.

The case was an ambiguous one throughout. Death was certainly not directly due to the heart affection; and yet before the operation was performed the patient was rapidly sinking from dyspnœa, due to an overburdened right heart. How aspiration of the left ventricle could relieve this and apparently prolong the man's life is, and probably always will be, a mystery to me.

CALCIFICATION OF AN ORANGE LYING FREE IN THE PELVIC CAVITY.

By JOHN A. PRINCE, M.D.,

SPRINGFIELD, ILL.

Miss B——, aged forty, had been a sufferer from ovarian trouble for some years, having pain mostly on the left side. During the last year or so she has suffered also from prolapsus uteri. Examination revealed the uterus studded with fibroid nodules of small size. I advised removal of the ovaries to stop the ovarian pain and avert the growth of the fibroids, and proposed also to do ventro-fixation for the prolapsus. On passing my fingers over the posterior surface of the uterus they came in contact with a hard body, loosely adherent, and easily separated from its attachments to the uterus. The right ovary was present and cystic. This with the tube was removed. The left ovary and tube were absent. All that remained was a short stump of the tube about one-fourth of an inch long.

On examining the hard body removed from the posterior surface of the uterus, it was found to be of the exact shape and size of the ovary. It was free in the pelvic cavity, save the very slight attachment to the uterus by its rough surface.

The ovary must have attained full size in its normal position, when from some cause it became detached with the tube, probably from some constricting agency, which has done a far neater amputation than could have been done by any surgeon. All vestige of any constricting band or of the amputated tube had disappeared. Ventro-fixation was done, and the wound closed. The patient is making a good recovery.

ANENCEPHALOUS MONSTER.

By J. M. PERKINS, M.D.,

LEBANON, MO.

On March 5, 1891, I was called to see Mrs. H——, aged twenty-seven, multipara. She and her husband thought, and all who had seen her thought she was going to give birth to twins on account of her unusually large size. From her appearance I thought so too, but on examination I changed my mind. She had short sharp cutting pains, commonly called by old women wiggling pains. I waited on her for three or four hours to see if pains would get harder and cause a dilatation of the os. I noticed her pinched features, which was unusual with her, and her great restlessness, which was gradually becoming more and more in any position. I concluded to rupture the membrane and relieve her of the amniotic fluid, which was excessive in amount. Labor pain set in a few moments after the membranes were ruptured. I waited a while, made another examination, and found that something was wrong, but what it was I could not at the time say. After great difficulty, having introduced my hand and made traction with the finger on the presenting part, I delivered my patient of an anencephalous monster.

There was no sign of a neck, except a depressed rin all round the place the neck should have occupie The body was rather short, about two-thirds of the dinary body of a well-formed fœtus, legs very long and sturdy, arms long and slender, male organs well developed, anus closed, mouth very large and opened like the mouth of a bull frog. Eyes well developed, but closed, nose flat and broad, ears back at point of scapulæ or nearly so; no occipital or frontal bones, eyes ran back to origin of optic nerve, the course of which could be traced with the index finger as there were no orbital bones.

On August 9th, prior to the birth of this monster, a picnic was had at which a brother of the mother of this monster drank too much and became engaged in an altercation with another intoxicated man, with the result that he was terribly whipped. Both eyes and the top of the head were bruised almost to a jelly, and he was also shot. I was called to dress the wounds of both men, and when I finished my work, the mother of this monster arrived from home, and seeing her brother in this terrible plight, fell on his neck and went into a fit of hysteria. I at that time did not know she was pregnant, or I should not have allowed her to have seen him. My opinion is that the impression made on the mother at this time was the cause of the non-development of the fœtus, as both the mother and father had always been healthy.

A CASE OF TREPHINING FOR FRACTURED SKULL.

By W. KIRKER BEATTY, M.D.,

SURGEON TO ANCHOR LINE OF STEAMSHIPS.

In reporting the following case, in many points open to criticism, my object is to illustrate the beneficial result obtained by immediate operation for depressed fracture of the skull.

July 13, 1895, four days from the port of New York, the following case came under my observation:

Michael McC——, an able-bodied seaman of twenty-one years of age, Irish by birth, a strongly built man, slow of action, and of a rather phlegmatic temperament, while at work on deck was struck on the head by a bolt (from a shackle) falling from aloft from the main trysail.

On reaching his side a few moments later I found him lying senseless in a large pool of blood with a ragged contused wound over the right parietal bone. Upon examination I discovered a considerable depression in the bone of an oval shape; the bone was much comminuted and closely impacted, so that it was impossible to loosen any of the fragments; the depth of depression was half an inch. His condition was that of such profound shock that I feared dissolution would occur before I could relieve him. After dressing the wound temporarily to check hemorrhage, I administered two milligrammes of the sulphate of strychnia hypodermically, and began preparations for operating.

Having no time for an elaborate sterilization of instruments and dressings, my main reliance for antisepsis was placed on carbolic-acid solutions, the proportions being roughly estimated. After administering chloroform until the patient was thoroughly anæsthetized, I gave the anæsthetic into the charge of the steward, quite an intelligent and capable man.

I commenced the operation by incision at either end of the wound, laying bare the bone for an inch at either end of the fracture. After carefully elevating the periosteum and turning it aside, I obtained a better view of the fracture; it was located in the lower portion of the right parietal bone, nearer its posterior than anterior border. Placing the trephine posteriorly from the fracture, I removed a disk of bone half an inch in diameter, which I immediately placed in a glass of water at about 37.8° C. (100° F.). I then inserted an elevator and removed the comminuted bone, placing the larger fragments into the water with the disk. After cleaning

away all visible fragments, with the aid of a probe bent at right angles, I removed several small spicula from between the dura mater and the calvarium. After the clearing of the dura I allowed none of the carbolized solutions to be used, relying solely on warm water, which had been previously boiled. When all active hemorrhage had been checked, I replaced the trephined disk and two of the larger fragments in as nearly their original position as possible, and closed the wound by continuous suture, dressing with carbolized cotton.

The immediate result of the operation was an obvious relief of the respiratory symptoms, which before the operation had been marked by great irregularity; after removal of pressure upon the cerebrum respiration became regular and easy.

The subsequent history was that of steady and uninterrupted improvement; he regained consciousness one week later, and in twelve days insisted on being allowed to walk. One week after the operation I removed the stitches, finding the wound had healed perfectly and the bone beginning to unite solidly. July 25th I removed him from the ship and placed him in the Colonial Hospital, Gibraltar, to convalesce.

During the operation, which of necessity had to be performed on the upper deck, only the crudest of antiseptical precautions could be obtained; had his condition permitted delay it might have been otherwise.

I attribute the gratifying result of the operation to the immediate removal of pressure from the cerebrum.

August 22d I was again in Gibraltar, where I learned that he had suffered no subsequent mental disturbance, and that he was in a perfectly normal condition of mind and body.

SPONTANEOUS RUPTURE OF THE BOWEL.[1]

By W. E. LOWER, M.D.,

CLEVELAND, O.

On August 21st, about twelve o'clock, a laborer, aged sixty-three, reported at my office, and stated that while lifting one end of a 24-foot plank he strained his left side.

He complained of considerable pain in the left iliac region, the pain extending into the left inguinal region. He was placed upon the table, and it was noticed that a considerable fulness existed in both iliac and inguinal regions, more marked on left side, and extending well over the pubes on that side. After satisfying myself as to the non-existence of a hernia, Dr. Bunts, who was in an adjoining office at the time, was asked to see the case. He, also, found no evidence of hernia. Upon closer inquiry relative to the fulness on the left side, the patient informed me that there always had been more or less fulness there. His pulse was 78 and of good volume. He was rather anæmic, which he stated was quite natural with him; of a rather waxy complexion, and had a somewhat pinched expression. His bowels had not moved on this day, but had on the day previous, although he was rather constipated. He was sent to his home and instructed to go to bed, a laxative was prescribed, and hot applications ordered.

In the afternoon he was still suffering considerable pain and vomited several times. He was given one-eighth of a grain of morphine, and ordered to take one such dose every hour until relieved.

In the evening, about seven o'clock, I was called to his home and found him suffering quite severely, pain extending over the entire abdomen, but most severe in the left iliac region. His abdomen was slightly tympanitic.

I again examined him carefully for hernia, believing from the nature of the injury and the symptoms present, there might be strangulation, but again failed to find any objective symptoms of hernia. His bowels not having moved, an enema was given, which caused a slight movement. His pulse was 98, and temperature under the tongue 99° F. His tongue was dry and covered with a heavy coating. This was noted when he reported at the office. Hot applications were continued and morphine as needed to relieve pain. The abdominal symptoms and the pinched expression pointed to peritonitis. I again saw him the following morning. He had slept but little during the night, but became quite easy in the early morning. Another enema had been given during the night, but failed to move his bowels. He had vomited frequently, a dark-colored vomit. The tympanitis remained about the same as on the previous evening; tenderness slightly diminished; pulse, 108; temperature under the tongue, 99.4° F.

There was great thirst. A diagnosis of probable septic peritonitis was made, though no satisfactory cause could be assigned. Hot applications and morphine were continued. About 6 P.M. I again saw the case, and found him in collapse; pulse, 150, and very weak; cold perspiration and extremities cold. Respirations, 30; and a persistent hacking cough was noted. He was rational. Enemata of milk and brandy were ordered. At eight o'clock Dr. Ceile saw the case with me. The question of operative interference was considered, but not thought advisable, on account of the condition of the patient and the hour of the day. Stimulating enemata were continued, and the case again seen about 10 P.M., with Drs. Bunts and Ceile in consultation. An operation was considered inadvisable, and the patient died at 2 A.M., August 23d, thirty-nine hours after receipt of injury.

Autopsy.—Abdominal wall above pubes œdematous; a considerable accumulation of adipose tissue gave the prominence in inguinal regions clinically noted; adhesions to the parietal peritoneum more marked on left side; the under surface of the diaphragm and the intestines adhered to each other. There was no gas in the peritoneal cavity, but about half a gallon of muddy fluid. A large amount of tenacious exudation at various places; very marked congestion of all the superficial coils of intestines, especially in the umbilical, left iliac, and hypogastric regions. A perforation presented, one-fourth inch in diameter, half an inch from the median line of the convex surface of the ileum, six feet above the iliac-cæcal valve.

The perforation was round, the margins of which were rounded and smooth. The mucous membrane for about an inch around the perforation was markedly congested; the wall of the intestine was not perceptibly altered in thickness. No evidence of ulceration. The perforation was the centre of an intense peritonitis; the immediate coils of intestine were intimately adherent, and a profuse plastic exudation covered this part. The entire intestinal tract was laid open and inspected. There were no ulcers, no thickening, but in places there were patches of considerable congestion. The mucous membrane was everywhere intact, and not easily stripped off. The appendix was normal. The diaphragmatic peritoneum was congested, covered with exudate, and could be easily stripped off. The liver rather large; the gall-bladder and bile-ducts normal; kidneys apparently normal. The bladder hypertrophied from an old inflammation; the prostate enlarged. There were no old adhesions and no excessive amount of gas in the intestines.

Diagnosis.—Acute septic peritonitis, caused by the spontaneous perforations of the ileum.

[1] Reported to the Cleveland Medical Society, September 14, 1895.

A Coroner's Jury in England once brought in a verdict that "a three months' old child was found dead, but there was no satisfactory evidence that it had ever been alive."

A CASE OF TETANUS (TRISMUS) WITH RECOVERY.

By CARL PROEGLER, M.D.,

FORT WAYNE, IND.

A TWO-YEAR-OLD child was caught with her right hand in a feed-machine and brought to my office with a badly mangled hand, index-finger nearly torn to the tendons, but no bones broken. The wound was treated strictly antiseptically, three silk sutures were used in uniting the loose skin of the finger, and then the whole hand was wrapped up in moist iodoform gauze. Redressings were always done antiseptically; after one week the stitches came out with hardly any suppuration.

Two weeks afterward the child was brought again to my office with confirmed trismus. The jaws were so firmly set that it was impossible to open them; opisthotonos occurred during the examination. The wound was completely healed. I prescribed chloralamid, five-grain doses, per rectum, every three hours.

Next morning the child was deeply narcotized, but the jaw was a good deal more relaxed, and she was able to swallow milk. I ordered the injection then every four hours. Recovery was complete, with the exception of an inability to swallow solid food, probably due to spasm of the œsophagus. With a few hypodermics of strychnia ($\frac{1}{60}$ gr.) this was overcome, and the child is now as well as ever. The wound was already healed when trismus occurred, therefore no bacteriological examination was made.

161 GRIFFITH STREET.

ABSCESSES OF THE EXTERNAL AUDITORY CANAL, FOLLOWED BY PERICHONDRITIS AURICULÆ.

By S. GOLDSTEIN, M.D.,

NEW YORK.

MR. L—— came to me on July 1, 1894, stating that some months previous he had suffered from what he termed "a boil in his ear." For this he went to a specialist for treatment. The abscess was incised and recovery was uneventful.

When I first saw him, on the above-mentioned date, he complained of stenosis of the nares, foul odors from the nose and mouth, and a discharge from both ears. Upon examination I found the occlusion of the anterior nares, due to extensive hypertrophy of the middle and inferior turbinated bones on both sides and ecchondroses of right and left sides of the septum; he also had an exceedingly large pendulous uvula and a follicular pharyngitis. Upon examining the ears I found a chronic suppurative inflammation of both ears, the discharge being more profuse in the right. At that time I advised the removal of the hypertrophied portions of the middle and inferior turbinated bones, the pendulous portion of the uvula, and curettage of the pharynx; also antiseptic treatment of the ear. To this he acceded. Upon completion of this treatment the discharge from the ears had almost ceased; in the meantime the odors had disappeared, and nasal breathing and drainage were well established. Unfortunately, my patient was unexpectedly compelled to leave town, and I did not again see him until May 26, 1895. He then complained of the discharge from both ears. For this I placed him upon appropriate treatment. He was improving steadily until July 1st; he then had a small furuncle on the concha of the right ear, which I incised, and from which a few drops of pus exuded. On July 5th he complained of pain over the right mastoid, cheek, and within the external auditory canal. I found the external auditory canal almost completely closed by a swelling in front of the tragus, and the meatus red and swelling quite extensively. Fluctuation was evident over and in front of the tragus and within the canal. I made an incision anterior to the tragus and within the canal, making communication between the incisions for drainage. A large quantity of thick, creamy pus poured out. I then curetted the part and drained with iodoform gauze. The patient was seen daily for a week. Each day the canal and abscess cavity were thoroughly cleansed. An uneventful recovery took place at the end of the second week. At that time there was still some discharge from both ears. For this I cleansed each canal every second day, and twice weekly made applications of pure iodine, with happy effect.

166 EAST NINETY-THIRD STREET.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

BRITISH ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE — ALARMING INCIDENT AT THE PRESIDENT'S ADDRESS—SCANDAL AT THE CANCER HOSPITAL.

LONDON, September 14, 1895.

THE British Association for the Advancement of Science is in session this week, the place of meeting being Ipswich, where the members have been heartily welcomed. Lord Salisbury retires from the presidency and Sir Douglas Galton takes this high office. He gave one of the least technical addresses that have ever been delivered from the chair. During his address he was seized with indisposition, and, to the great alarm of the audience, unable to proceed. He had been reading carefully for about an hour under a rather powerful argand burner, when he faltered, stammered, and then stopped amid a dead silence. He was seen to be leaning rigidly against his desk with his papers still in his hands, which were trembling. Sir John Evans, who was near, sprang forward, and so did the Mayor, who is a medical man. They assisted the President, who tried to utter a sentence, to his chair and restoratives were administered. It was a scene of a most painful and agitating kind. It was presently announced from the platform that there was no danger to Sir Douglas, and the strain of the audience was thereby greatly relieved. It was then suggested that the remainder of the President's address should be taken as read, but Sir Douglas had by this time sufficiently recovered to express a wish that Sir John Evans should read for him the concluding pages. This accordingly was done, while the President, pale and looking worn, sat smiling and listening. At the conclusion there was a burst of applause which could not be exceeded, and which was probably none the less hearty as it was a reaction from a state of consternation. A vote of thanks was carried with enthusiasm, and then the President rose and slowly approached the desk and said he wished to express his thanks, but would be glad under the circumstances to be excused. He was able to leave the platform leaning on a friend's arm, and the audience quickly dispersed.

The next morning (Thursday, 12th) the first question in all directions was as to the health of the President, and great was the satisfaction felt on the announcement that the faintness was but a temporary indisposition, and that Sir Douglas was sufficiently recovered to fulfil his engagements in connection with the Association.

The meeting at Ipswich has been successful: it has been conducted in a business-like manner and the sections have been well attended. There are nine of these and each has its presidential address—rather a surfeit

of addresses for those who take an interest in many subjects. But this arrangement enables a number of experts to bring before the public the progress made in their several departments, and thus scientific matters are made to interest wide audiences. This is, of course, desirable for science, in which respect this Association stands on a different plane from that of its imitator—the Medical—which should not approach the public, its proceedings being only for the profession. I think, therefore, these sectional addresses may do much good, but would be better omitted in the case of the Medical Association.

Some three years ago a dispute at the Cancer Hospital led to a trial for libel, in which Mr. Jennings sought to vindicate his character. He had advised a woman to submit to amputation of her arm. Some of his colleagues disagreed with this recommendation, and somehow the matter was brought before the managers, who dismissed Mr. Jennings. He is now asking for some apology or an explanation of the curious alleged sequel. It is stated that the poor woman was afterward readmitted to the same hospital, that amputation was performed there, that she died there, and that the certificate of death assigns as the cause morbus cordis! More facts should be forthcoming promptly if the management or staff expect to vindicate themselves. Who signed the certificate? Who amputated? If Mr. Jennings made an error of diagnosis, though he was supported by eminent surgeons, and was justly dismissed for it, what should be the penalty of amputating for morbus cordis, and who is the proposer of this treatment?

CHOLERA IN KOREA.

INTERESTING FACTS CONNECTED WITH ITS WIDE PREVALENCE THERE—THE REGULAR MORTALITY—THE EFFICACY OF SALOL IN ITS TREATMENT.

(Special to the MEDICAL RECORD.)

SEOUL, KOREA, August 19, 1895.

It has been my rare privilege, during the epidemic of cholera now about over, to see more of the disease than anyone else, and yet in the month that we have had it I have been enabled to personally see only about five hundred cases, though the total deaths in the city and vicinity, comprising a population of about three hundred and fifty thousand people, have been at least six thousand. The same ratio in New York City would be about ten thousand a week. During this time I have had charge of the only cholera hospital now in operation, another one, run by a number of physicians, having proven impracticable, as they hadn't many conveniences and were unfortunate in having many dying patients sent to them—a condition from which we did not escape either—and consequently their death-rate was so high, sixty-five or seventy per cent., that it had to be closed. We were fortunate in reversing those figures, and have had from sixty-five to seventy per cent. of recoveries, and as I think it was in great part due to a certain plan of treatment, I think it is appropriate for me to send you a brief statement with a couple of typical cases. In the hospital here I have had but one hundred and forty odd cases (some were indeed very odd), the others were in the other hospital, which treated about one hundred and twenty-five, and around town, from the hovels of the poor to the palace of the king, where I was on duty for a while. In a general way the disease doesn't seem to be particularly virulent, though it has swept over certain portions of the city like as if a wind had carried the germs.

In regard to the disease as seen here, I am inclined to think that of one hundred people attacked ten will recover without any treatment at all. A sort of survival of the fittest proposition which may, or may not, stand against theoretical arguments. Without the use of drugs by the mouth, using only the saline or tannic-acid injection, then about twenty per cent. can be cured. With all the drugs usually used and all the methods too, then fifty per cent. will recover; but with salol and the rest, I am strongly of the opinion, proven by our records, that eighty or ninety per cent. can be cured. The limited supply we had of this valuable drug enabled us to use it in but few cases, and the percentage of cures in those was over ninety per cent.

It would be tedious and lengthy to go into the details of the symptoms, complications, and treatment of the various patients, but a general idea of the routine carried out from the two cases is here submitted, though the majority did not receive salol, as we hadn't it to give.

In regard to the complications we had some very diverting ones. Pregnancy was a common condition in the women, and they usually died. One, however, had a miscarriage at the fourth month, and I said if she would only have puerperal fever, that I thought she would recover. There was no evidence of fever, but the woman came out of cold sweat, collapse, and a most unfavorable condition, and recovered. Two cases dropped off suddenly from heart failure and one from cystitis. In one case of retention, I drew off sixty ounces of urine.

CASE XLIV.—Kim Wun Pal, male, aged forty-eight. Received at the hospital at 4.30 P.M., August 8th. Had had severe vomiting and continuous watery stools since morning. Symptoms of complete collapse. There seemed to be no chance at all for the man's recovery, so I wrote on the record paper, "No pulse, collapse, dying condition. We only receive him because——." Nevertheless, I set the Korean nurses I have trained at work. Gave sixty minims sulphuric ether hypodermatically and three pints of a saline solution (3 j. salt to the pint) high into the bowels, using two long soft-rubber catheters, enteroclysis as it is called, being particular as to all the details of the procedure. At 5.20 his condition was unchanged, so I practised hypodermoclysis, injecting three pints of the saline solution, at a temperature of 104° F., under the abdominal tissues. I did this many times on many patients, but was unable to carry out the fine details of antiseptics usual. My water wasn't sterilized, nor the body at the point of puncture washed. I had no bad result in any case, except a slight inflammation in one where I injected into the thigh instead of into the abdominal space. In regard to the enteroclysis, I think it ought to be a most valuable antipyretic procedure, having the water at whatever temperature is appropriate. I also gave twenty-five more minims of ether, having had the patient vigorously rubbed with alcohol in the meantime; at 6 P.M. enteroclysis, three pints.

The characteristic pains and cramps which they appropriately call "snakes," as the muscles contract into hard knots, and seem to creep up, so that many patients are brought in with cords tightly bound around their legs, now supervened. For the relief of this I gave $\frac{1}{4}$ grain of morphine, our rule being to use morphine only when absolutely necessary. At 10 P.M. enteroclysis and brandy at intervals. At 1 A.M. there was as yet no reaction and no pulse, but the vigorous measures were continued. At 6 A.M. the pulse became barely perceptible and the body slightly warm; 30 grains of salol were given, which was continued in 15-grain doses every three hours for several doses, enteroclysis with the saline fluid, cracked ice for vomiting and to relieve the thirst, milk, rice-water, brandy, and beef-tea. There were no other unusual symptoms. The man made an uneventful recovery, and in a few days walked home well, stopping at my sarang as he went out to make his profound bows and orientally exaggerated thanks. Indeed, this feature has been one of the most pleasing and diverting of all.

The other case in which I think the recovery entirely due to salol, was in this wise:

Kim Gung Yun, male, aged twenty-six. Frail, weak

young man, received at 2.30 P.M. on August 5th. He was much emaciated and looked as if he had been through a threshing-machine. His mother and other members of the family had just died of cholera. His severe symptoms had only commenced in the morning, and as yet he had had no vomiting. The pulse was good. I ordered at once the saline injection to thoroughly wash out the bowel, and gave a dose of sulphuric acid (dilute) and camphor and 10 grains of salol. At 6 P.M. enteroclysis, sulphuric acid, and camphor, internally. The man grew rapidly worse, vomiting came on and was uncontrollable. At midnight, gave 30 grains of salol, and had the usual vigorous rubbing with alcohol kept up constantly. Champagne was given at intervals. At 6 A.M. 5 grains of salol. At 7 A.M. those awful cramps and pains doubled him into a knot, and I gave $\frac{1}{4}$ grain of morphine. At 9 A.M. the pulse was barely perceptible, so I gave forty minims of ether hypod., and 20 grains of salol. At 10.30, 10 grains of salol. At 12, $\frac{1}{8}$ grain of morphine and sixty minims of ether. Enteroclysis was repeated at regular intervals. At 3 P.M. $\frac{1}{60}$ grain atropia in thirty minims of ether. From 3 to 8 P.M. we kept up the work, when the nurses and all gave him up and sent for his father and friends, who came in the morning, bringing the grave clothes ; but the man wasn't dead yet. At 3 A.M. there was a slight improvement, the salol was continued, as was the enteroclysis and other routine of food and stimulation, and on the sixth day the man was discharged well. There were scores more like these two cases, presenting many interesting details, but alike in general particulars. The last case illustrates the general symptoms as we find them in this epidemic. As to salol, it is not necessary for me to more than mention its physiological action. It beads up into forty per cent. of carbolic acid and sixty per cent. of salicylic acid by the action of the pancreatic juice, and so comes in contact with the comma bacillus and when it does most live to coagulate. In my hands it has proven a most remarkable remedy in this affection. I used a small quantity of the sulpho-carbolate of sodium, all I could obtain, in a limited number of cases, and wish to report most satisfactory results. I am inclined to think it may be as valuable as salol.

J. HUNTER WELLS, M.D.

ANOTHER BERIBERI SHIP.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR : The bark Lottie Moore, one hundred and seventeen days from Aleppy, India, opposite Ceylon, arrived in New York harbor this morning from Barbadoes, where she had put in, with her entire crew, all Europeans, sick of beriberi. There were sixteen persons, all told, on the ship. All were affected except the wife and child of the captain. Before reaching Zanzibar, two months and a half after the start, the first cases appeared, two men in the forecastle, where eight men were quartered. The captain and the officers were quartered in the stern. The voyage was exceptionally dry. At no time did the water on the decks reach to the hatches, which shows that very little rain fell. The cargo consisted of eight hundred tons of coir garu (cocoa fibre), some ginger, cocoanut oil and gamboge. The cocoa fibre sweated. I found in the hold all the iron carburetted. The ship's carpenter told me that on opening the hatches large volumes of steam streamed from them. He states that last year he was on a boat charged with a similar cargo ; this ship also had to put into Barbadoes, where the captain and two of his men died of beriberi. The same man was on board of a coffee ship, twelve years ago, when three men were stricken with beriberi. This coffee cargo had "burned" on the voyage, and the crew, not knowing what the disease was, attributed the outbreak to that circumstance.

I may add that here again, then, we find evidence that the sweating or fermentation of a vegetable cargo is the main cause of beriberi.

ALBERT S. ASHMEAD, M.D.

NEW YORK, September 12, 1895.

CRANIOTOMY.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR : Dr. F. W. Higgins, in his article in the MEDICAL RECORD of September 14th, quoted Balestrini on his investigations of infanticide and abortion as saying that what is killed is not a man, but a being inferior in the zoölogical world. Now I say that this is a dangerous and most abominable doctrine, particularly at a time when the "fashion of abortion" is on a fair way to die out in this country. I hold that as soon as the two elements meet in copulation there is life, and it is criminal to destroy it, whether one month old or more, unless justified by prevailing grave conditions.

In my opinion craniotomy is justified, 1, when the fœtus is dead ; 2, when abdominal section and symphyseotomy are out of the question.

Referring again to the doctrine of Balestrini, I will say that this will be balm to abortionists, and that by it they will have a means to defend their nefarious practice. If it is inferior, it is only so far inferior to the infant as the infant is to the man.

CARL ENGEL, M.D.

MINDEN, IA.

THE ELECTRO-MAGNET FOR THE REMOVAL OF FOREIGN BODIES FROM THE EYE.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR : Please allow me space through your columns to explain to Dr. S. Mitchell, of Hornellsville, N. Y., why I neglected to mention the electro-magnet in my report of "Accidents to the Eye while Chopping with a Hoe." Had my theme been "Foreign Bodies in the Eye and their Removal," then perhaps it might have been a crime not to have mentioned the use of the electro-magnet, but as I only intended to show the frequency of accidents to the eye while chopping with a hoe, I ask for pardon. In looking over my case-book it so happened that I selected cases in which I did not think it necessary to use the electro-magnet. Had I reported all of my cases of this nature, the use of the electro-magnet would have been mentioned, inasmuch as I really own one, and have at various times used it, and am sorry to have to report that at various times I found it useless. I bought the instrument during a sojourn in London in 1880. Several times have I witnessed Mr. Nettleship, Lawson, Tweedy, and other surgeons to Moorfields, and equally as competent and celebrated men in the different cities of America, manipulate and manœuvre about in the vitreous with an electro-magnet for *corpus alienum* of steel, with more failures than success. I myself have tried to remove pieces of steel with the magnet from the vitreous, only a limited number of times, from the fact that most of my cases when presented had commencing or advanced panophthalmitis, and experience, if nothing else, dictated to me that the electro-magnet would be of no use, even if the extraction of the foreign body were certain. But in recent cases—before irido-cyclitis, suppurative chorioditis, or panophthalmitis has set in—a careful use or trial of the electro-magnet is certainly advisable. Two weeks ago to-day a patient—a stone-cutter—consulted me, saying that he had "a piece of grit in his eye." The accident happened the day before. A bead of vit-

reous could be seen protruding from the wound in the sclerotic, made by the foreign body. I was satisfied that the offending member was a piece of steel from the hammer or chisel, and was lodged in the vitreous. I at once extracted from my armamentarium an electro-magnet, and with competent assistance used every effort to extract the piece of steel, but am sorry to have to add we made a complete failure. Had we been fortunate enough to have extracted it, I am doubtful as to the saving of the ball in this case, as I suspected incipient panophthalmitis, and advised enucleation, which, however, was refused. A solution of atropia and anodyne, and cold applications were advised. In three days the patient returned with an advanced case of panophthalmitis, and eager to have the ball removed, which I did, and afterward found the foreign body—a piece of steel, the size of a large pin-head, in the vitreous. My reason for not using the magnet in cases of foreign bodies in the anterior chamber of the eye is simply this: I much prefer to use forceps. Why not have an electro-magnetic pair in our armamentarium? I might announce, like the doctor, "I am now," and have been for years past, "using" the alternating current "in my office, and by means of a converter, manufactured by a mechanic in this city, I am able to use it for all kind of cautery work," and pardon me for saying that lots of this kind of work might be left undone, with no detrimental effect to suffering humanity. The alternating current is not suitable for the use of the electro-magnet, in consequence of which I am forced to resort to various kinds of storage batteries, and this may be the cause of my non-success with the use of the electro-magnet.

WILLIAM L. BULLARD, M.D.

COLUMBUS, GA.

"*THE*" WRITER, NOT "*A*" WRITER.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: My attention has just been called to the fact that in my article upon appendicitis in your issue of the MEDICAL RECORD for August 31st a misprint occurs, which changes the meaning. I am made to say, of the technique which I there advise, in appendix-operation, "It has recently been described by *a* writer in the *International Journal of Surgery*; together with a study of these eleven other methods."

This should read "*the* writer," as the article in question in the *International Journal* was written by myself. I ask for correction of this typographic error simply because it leaves me in the apparent attitude of using and quoting the original work of another man without doing him the justice to mention his name.

Respectfully yours,

ROBERT H. M. DAWBARN.

September 20, 1895.

"A SHORTER SCALE FOR THE THERMOMETER."

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: Allow me to suggest to Dr. Elmar C. Fahrney, and to those who may agree with him as to the desirability of having the thermometer scale commence at 98° instead of 95° F., the utility of studying subnormal temperatures. I could better agree with him in his letter to the MEDICAL RECORD of August 31st, to cut down the top of the scale—though I did run across a temperature of 109° F. a while ago in a scarlet-fever case—than to chop off the scale below 98°. A physician who sees his chronic cases after 10 A.M., as most of us do, is not likely to catch their lowest temperatures. Let such patients have a thermometer and keep their own records at seven, ten, one, four, and eight o'clock, and a different phase may be put upon their thermal condition. My own rule is to choose the hours 8 to 9 A.M., 1, 4, and 8 P.M. In tuberculosis especially we ought to take cognizance of both swings of the heat pendulum.

Of a dozen cases of tuberculosis now under treatment, morning temperatures have been found in the last fortnight in at least one-half, ranging from 94½° to 97° F. Under tuberculin or antiphthisin treatment this decadence in the morning record is especially noticeable when the treatment is proving effective, and it is a good sign to see the morning average rise as the evening record lowers under the continuance of any remedial means.

CHARLES DENISON, M.D.

DENVER, COL.

New Instruments.

THE AUTO-STERILIZING THERMOMETER CASE.

THIS is a new invention which furnishes the physician with a reliable and never-failing means for preventing the transmission of disease by means of the thermometer. It keeps the instrument sterile and always ready for instant use, without any special attention on the part of the physician.

Government tests of the auto-sterilizing thermometer case, made under the direction of the Surgeon-General of the United States Army, by Dr. Walter Reed, the curator of the Army Medical Museum, show that although the thermometers were freely smeared with solid cultures of bacillus diphtheriæ, staphylococcus pyogenes aureus, and streptococcus pyogenes, absolutely no growths occurred after an exposure of the thermometer for twenty-five minutes in the auto-sterilizing thermometer case.

As the tests were many and exhaustive, extending over the period of a month, from June 21, 1895, to July 23, 1895, they appear to prove conclusively that the auto-sterilizing thermometer case will destroy all germs of disease with a maximum exposure of twenty-five minutes to the action of the vapor, and for the ordinary use of the thermometer ten minutes' exposure is all that is necessary to render it aseptic.

The thermometer rests in a receptacle like the hard-rubber cases usually sold with thermometers, except that at the lower end of the case is attached an extra hard-rubber chamber one-half inch in depth, which contains a small pledget of absorbent cotton soaked with the glyceraldehyde. The fluid being very volatile, the vapor rises to the interior of the case proper through openings provided in the bottom of the case, and keeps the thermometer sterilized without other attention than recharging once a week with a few drops of glyceraldehyde.

Glyceraldehyde is composed of several germicidal properties, the base of which is formaldehyde.

Dilatation of the Stomach.—At no distant day dilatation of the stomach will be successfully treated by gastro-enterostomy.—WINIWARTER.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending September 28, 1895.

	Cases.	Deaths.
Tuberculosis	103	102
Typhoid fever	36	15
Scarlet fever	25	2
Cerebro-spinal meningitis	5	4
Measles	56	3
Diphtheria	121	15
Small-pox	1	0

Some Recent Views on Immunity.—At a late meeting of the Epidemicological Society of London (*The Lancet*) Dr. J. W. Washbourn read a paper on the subject of immunity, which was, he pointed out, a problem of the deepest scientific interest, and of no less practical importance because the antitoxin treatment of diphtheria, probably the first step toward an entirely new field of therapeutics, was the direct outcome of the close study of its phenomena. The first fact to be taken into consideration was that pathogenic bacteria produced their effects on the organism by means of poisons or "toxins" which they elaborated in the fluids of the body, as was well seen in the production of all the symptoms of diphtheria or of tetanus by the inoculation of sterilized culture fluids, without a trace of the bacilli themselves. These toxins were intensely virulent, but others, as that of the pneumococcus, were extremely feeble. The bacilli of diphtheria and tetanus when inoculated did not invade the vascular system, but multiplied in and around the seat of inoculation only, though the toxins they produced were diffused throughout the body. These might be taken as types of toxic diseases; though in the case of tetanus the inoculation of washed spores into a healthy wound produced no effect unless the tissues were lacerated or suppurating, or other bacteria were introduced at the same time and place. In septic diseases, on the other hand, the toxins were feeble, but the bacteria invaded every tissue and fluid of the organism. This was well seen in the study of the coccus of pneumonia in the rabbit. Some, as septicæmic, partook of the character of both, and some acted in one way or the other under different circumstances. We must consider the power of the body to destroy the bacteria or inhibit their growth, and the power of resisting the effects of their toxins, the former factor being most important in the case of the septic and the latter in that of the toxic diseases. Immunity might depend on either condition or on both. It was either natural or artificial and acquired. Fowls, pigs, and white rats were immune to anthrax; birds generally to the pneumococcus; mice to the toxin of diphtheria; and fowls to that of tetanus, just as they were to large doses of morphine. They would, however, succumb to anthrax if depressed by cold and ill fed. An artificial immunity might be acquired in several ways, as by inoculation with a mild or artificially attenuated virus, or by minute doses of a virulent one, or by non-fatal doses of the pure toxin. Anthrax virus could be attenuated by cultivation at a high temperature or by the addition of certain antiseptics. As a rule, immunity obtained by means of the toxins was less permanent than that from inoculation of living microbes. Time was required to establish immunity by means of toxins, and such immunity did not last long, both periods being longer the greater the effect of the inoculation. It was easier to render an animal immune to fatal doses of the living bacteria than to those of the toxin; and when this latter immunity was obtained that to the bacteria was also, but the converse did not hold good. A fallacy of observation might, however, arise from the fact that living bacteria were often retained in the tissues long after apparent recovery, and called into renewed activity by the injection of toxin, they and not it being the cause of the subsequent fatal attack. In some few cases a very transient immunity had been produced by the intra-peritoneal injection of dead bacteria, etc. But of infinitely greater value was that conferred by injection of the serum of a highly immunized animal. The immunity was of far shorter duration than that produced by vaccination, but this method had a therapeutic as well as or even greater than its prophylactic, and unlike vaccination was available after the disease had developed. This was the antitoxin treatment of diphtheria and tetanus. Turning to the properties of the cells and fluids of the body in their relation to bacteria, Dr. Washbourn referred to phagocytosis as the most seductive theory of immunity. To Metschnikoff, who had studied the process throughout the animal kingdom, we owed all our knowledge of the subject. The amœba, as was well known, was capable of surrounding and digesting particles of food, including living bacteria. Among these Metschnikoff had observed a small unicellular micro-organism, the microsphæra, which, however, instead of being digested multiplied within the amœba and ultimately destroyed it. Such a struggle between the invading microbes and the protoplasmic cells of the body occurred, according to Metschnikoff, in every case of infection, ending in recovery or in death, as the cells or the microbes were victorious. The struggle and the alternative results were well seen in the daphnia, a small freshwater crustacean, and the parasitic monospora, which entered the tissues from the alimentary canal, and in a large number of the invertebrata phagocytosis played an important part. Among vertebrata the phagocytes belonged mostly to the class of leucocytes, which Metschnikoff divided into lymphocytes, eosinophile, neutrophile, and mononuclear leucocytes. Of these the two latter, together with the endothelial cells of the lymphatics and kidneys, were phagocytic, even when removed from the body, and that they were capable of thus devouring bacteria in the living animal was easily proved by experiments, such as the introduction of anthrax bacilli under the skin of a pigeon, or of those of tubercle into the blood of a rabbit, when they would be found to be taken up by the leucocytes and by the endothelium respectively, and successful cultures from such leucocytes showed that the bacteria might resist digestion for some time. The migration of leucocytes through the walls of the vessels in inflammation around the seat of an inoculation was due to a power possessed by various substances of attracting or of repelling amœboid cells, and known as positive and negative chemiotaxis. It could be studied in certain protozoa, as the myxomycetes, and in the vertebrata by inserting under the skin capillary tubes open at one end and containing chemical substances. On removing the tubes after some days, the contents, if positively chemiotaxic, will be filled with leucocytes. That the blood and lymph serum had bactericidal powers was first observed by Nuttell, and carefully investigated by Buchner, Behring, and others. If serum were inoculated with a cultivation, and the number of bacteria present estimated day after day by plate cultures, it was found that they gradually fell off until they disappeared altogether, or after having sunk in number for a time began to increase until they were more numerous than at first. It has been suggested that the serum contained a bactericidal substance called "alexine," and that the bacteria secreted an antagonistic 'lysine;" both were hypothetical, but the fact remained that bacteria, if numerous, could resist the undoubtedly bactericidal action of the blood, which was also very easily destroyed by physical agencies, such as the exposure of the serum to a temperature of 60° C. The bactericidal property was most conspicuous in inflammatory exuda-

tions, and was doubtless due to some substance secreted by the leucocytes, among which Hankin first indicated the eosinophile cells as the most active. But the serum was not merely bactericidal; it could be made antitoxic. Behring and Kitasato were the first to show that the serum of animals immunized by inoculation to the poison of diphtheria or tetanus possessed the power, when inoculated into others affected with the respective diseases, of neutralizing the poison and cutting short the morbid process; and the more frequently the immunized animal was injected with the toxin the more powerfully antitoxic its blood became. Ehrlich had shown that two vegetable poisons, ricine and librine, acted in a strictly analogous manner. Serums were thus antibacteric or antitoxic, the latter being antibacteric also. The bactericidal property of a serum was very easily destroyed by heat, but the antitoxic or protective property was not, and the substance in which it resided could not be precipitated without losing its efficacy. It was scarcely necessary to state that all antitoxins were specific or efficient against no toxin but that of the disease whence they were derived. Such were the factors in immunity—viz., phagocytosis, bactericidal substances, and protective serums, the last of these being outside of the question of natural immunity. Yet the problem of natural immunity was a complex one, special factors coming in; thus the low temperature of the frog's blood enabled it to resist inoculation with tubercle bacilli, and fowls were unaffected by tetanine as they were by morphine. The blood serum of white rats destroyed anthrax bacilli even out of the body, but their resistance to the action of the pneumococcus could not thus be explained. All such cases Metschnikoff would refer to phagocytosis, but marked phagocytosis might occur and death yet follow; indeed, in the case of rabbits infected with anthrax, the bacilli had been seen to escape from the interior of the phagocytes and multiply in the fluids. Again, in the exudation around the seat of inoculations many of the leucocytes were not phagocytes, and the exudation serum might be a powerful bactericide. Both agencies were involved in the resistance offered to infection and phagocytosis, very rarely alone. The problem of acquired immunity was further complicated by the introduction of a new and artificial factor—the protective power of the serum. An antitoxin, as that of diphtheria or tetanus, neutralized the paralyzing action of the toxin on the cells, allowing phagocytosis to have full play; for the serum of immunized animals had no bactericidal properties, and the spores of tetanus, if washed free from any trace of toxin and introduced into the body of a susceptible animal, were speedily ingested and destroyed by the phagocytes. Immunity acquired toward the septic diseases was even more obscure and complex, so that, pending the results of experiments which might throw light on the subject, it was better to refrain from conjecture.

The Section on Diseases of Children of the British Medical Association.—The subjects for discussion included "Congenital Syphilitic Manifestations in Bones and Joints," introduced by the President of the Section, and the treatment of "Hernia in Children." There was a very good attendance of members, and, the subjects being mainly of a surgical nature, many well-known surgeons contributed to the discussion. The president, in opening the proceedings, gave a short review of the work done by the Section in past years, which, though including a very wide range of subjects, had still left undiscussed a large number of most important questions of disease as occurring in children. He was in hopes that a section of such importance as this had established a permanent place in the proceedings of the Association. The president then opened the discussion on "Congenital Syphilitic Manifestations in Bones and Joints," with a highly interesting paper in which, after alluding to the researches already made in this country, he proceeded to discuss the pathology and clinical features of the atrophic and osteophytic varieties of the disease. The relation of rickets to congenital syphilis was also very fully discussed, especially with reference to the causation of cranial bosses and cranio tabes, and to the occurrence of chronic effusion into joints. Other speakers were Mr. Frederic Eve, who continued the discussion of these last-mentioned points; Mr. D'Arcy Power, who quoted instances showing the difficulty of diagnosis between syphilitic and tuberculous joint disease; Mr. H. B. Robinson, who discussed the order in which changes in the bones begin to appear; Dr. Thomas Barlow, who laid stress on the modification effected in cases of rickets by the existence of congenital syphilis; and Mr. H. Stansfield Collier, who described three cases of syphilitic effusion into joints unaccompanied by any previous bone disease. Mr. Rushton Parker (Liverpool) read an interesting paper on the "Treatment of Hernia in Children." During the last four years he had operated on forty cases, all males, and all for inguinal hernia, in some cases double; out of these he had had two fatalities. He preferred not to operate if the patient was under six months, except in urgent cases. He considered the chances of recurrence in children very small. He advocated Macewen's operation as the most secure, if not the easiest, method. He laid great stress on prolonged rest in the recumbent position after operation—six weeks, in children over six years of age. Mr. C. B. Lockwood emphasized the difficulty of completely separating the sac from the spermatic cord in young children. Mr. John Langton advocated treatment by truss only in a large majority of cases. Professor William Macewen spoke of the impossibility of dealing effectively with hernia in hospital practice by means of a truss—an opinion which was endorsed by every speaker present. He considered the delicate tissues of children were quite reliable for this operation, and in about thirty cases operated on by him had met with perfect success. Dr. Ward Cousins considered the operation in children over twelve months old eminently satisfactory, and gave an interesting account of his own method of procedure. Mr. J. Macready, Mr. F. A. Southam (Manchester), Mr. H. P. Symonds, Mr. Reginald Lucy (Plymouth), Mr. Damer Harrisson (Liverpool), and Mr. H. Waterhouse, all contributed to a highly interesting discussion, which included methods of operation, kind of sutures, dressings, etc., advocated by each speaker. The president referred to the frequent occurrence of strangulated hernia in young children. A case of congenital syphilis of the tongue was shown at the conclusion of the meeting by Mr. Jackson Clarke. Dr. J. Kingston Barton introduced a discussion on the "Doses of Various Remedies Suitable for Children at the Several Ages," urging that sufficient indication was not given in the "British Pharmacopœia" of the various drugs to which children were peculiarly susceptible, and that an additional list of doses suitable for children should be given, having special reference to age. Mr. Barton proceeded to give a list of twenty-seven drugs, which, in his personal experience, had required either to be increased or decreased much beyond the limits usually recommended. In his experience belladonna was an overrated drug, and its ill-effects were often more marked than the good it did. He advocated a smaller dose. With regard to a general rule of dosage, he recommended one-twelfth of an ordinary dose for a child one year old, and for under that age a reduction reckoned by the months of the child's life. The president, in commenting on the use of chloroform as an anæsthetic for young children, expressed his preference for ether whenever possible. Dr. A. Foxwell said that he agreed with Mr. Barton in advocating small and frequent doses as a rule. Dr. Dawson Williams said that he altogether doubted the age-limit in the administration of drugs. In his experience it was

useless to give too minute doses; especially in the administration of antiseptics and of mercury, he believed in large doses. Dr. Leech (Manchester) pointed out that the doses in the "Pharmacopœia" represented average doses. Arithmetical calculations were of very little value; physiological considerations were more important. Dr. N. J. Tirard said that the main considerations should be the nature of the patient and of the disease, as well as the purpose for which the drug was employed. After some discussion, the following resolution was carried: "That this Section thinks it desirable that in the new edition of the 'British Pharmacopœia' the maximum doses of powerful drugs suitable for children at various ages should be indicated." Mr. E. Cautley read a paper on the "Value of Trephining in Tuberculous Meningitis." Mr. Herbert Waterhouse and Mr. D'Arcy Power continued the discussion. Mr. Nicholas Grattan (Cork) showed an apparatus for osteoclasis, and Mr. C. W. Cathcart (Edinburgh) showed a simple form of milk sterilizer. Mr. C. B. Lockwood reported a case of hernia of the ovary in an infant with torsion of the pedicle. Dr. J. Walter Carr read a protest against the term "consumptive bowels," and Mr. Telford Smith communicated the "After-history of Two Cases of Craniectomy." A vote of thanks to the president, proposed by Mr. D'Arcy Power and seconded by Mr. C. W. Cathcart, ended the proceedings. — *British Medical Journal.*

A New Treatment for Fever.—A new curative treatment has been discovered by a Transvaal doctor. Having noted the fact that milk absorbs poisonous germs from a bucket, he decided that it might be possible to turn this germ-absorbing power to a therapeutic account. He put his ideas to the test, and now asserts that he has cured persons of small-pox, fevers, diphtheria, and other maladies by simply wrapping them in milk sheets. The patient is laid on a mattress covered with blankets, and is packed in a sheet just large enough to envelop the body. This sheet has first been saturated in a pint and a half of warm milk, and is applied to the body without wringing. After this treatment, which lasts about an hour, the patient is sponged with warm water, or is put into a warm bath.—*Medical Press and Circular.*

A Claim to Priority in Vaccination.—In the *Ugeskrift for Läger* Dr. Friis advances a claim on behalf of a Holstein schoolmaster named Peter Plett, to the honor of priority in the discovery of vaccination. Jenner's first vaccination was, he says, performed on May 14, 1796, but Plett had already done it in 1791. The latter was a tutor in a family at Schönweide, in Holstein, in 1790, and while there he heard that it was a matter of common knowledge that the milkmaids who had previously been infected with cow-pox never caught small-pox. Having by chance seen a medical practitioner perform inoculation, Plett conceived the idea that cow-pox lymph might be used for the purpose of conferring protection against small-pox. In 1791 he was at Hasselburg, and an epidemic of cow-pox occurring among the cows on a farm, he told the children under his charge to rub their hands with matter from the pustules; as no result followed he himself vaccinated three of them without the consent or knowledge of their parents. He used a table-knife for the purpose, making the incisions on the back of the hand, between the thumb and the forefinger. The operation was successful, and a year later, when the other children of the family suffered from small-pox, the three who had been vaccinated by Plett remained free from the disease. There appears to be no record of his having performed any other vaccinations.

Professor Heim on Suicide.—What ought to be done by the Swiss authorities, we wonder, to Professor Heim, the savant, for his speech at the Alpine Club in Zürich? Only a week or two ago it was decreed that the Swiss press should be silent concerning suicides, for newspaper reports of suicides gave a stimulus to some people to go and do likewise. And here is a Swiss scholar setting forth at a public meeting, and with reporters well to the fore, the fact that one of "the most convenient, elegant, and agreeable" of all manners of death is that which follows a fall from some Alpine height. There is neither physical nor moral suffering, in Professor Heim's opinion, in being hurled through space; only a "delicious, fine taste of the celestial beatitudes." But since the hurling through space is only part of an Alpine accident, it would be interesting to know a little more of the sensations which result when the body of the "accidentee" comes in contact with the rocks, and when he arrives at the bottom of a precipice, mangled and bleeding, and not yet dead. It will be asked how Professor Heim obtained his information on this subject. By plebiscite, of course. But whether it is quite fair to conclude from the testimony of those who have recovered after an accident that dying by Alpine accident is *une aimable façon de mourir*, is to be doubted. A more satisfactory way would perhaps be to consult the spirits who have been despatched into Borderland after the chute. We commend the idea to Mr. Stead.—*The Westminster Gazette.*

The Sensation of the Stomach and Disordered Digestion.—Dr. Sollier has made a study of nervous dyspepsias. He says that the sensory innervation of the stomach derived from the sympathetic may, when disturbed, lead to modification in the gastric chemistry. The secretory functions of the stomach depend on the nervous system as well as on the state of the glands. The sensation of the stomach may be reflex or direct. (*The British Medical Journal.*) The former is better known; it leads to the movements of the stomach and also to secretion. If the stomach is insensitive to the contact of food-stuffs, the glands are not put into action. The stomach has also a sensation proper to itself, and thus heat and cold can be appreciated. This sensation is not so obtuse as has been thought. The most special sensation of the stomach is in respect to food. The sensation of hunger disappears when the stomach becomes anæsthetic. Thus, without its own proper sensation, there could be no feeling of emptiness, as in hunger, nor yet of satiety, and, without its reflex sensation, no secretion and no motion. There is no subordination of one form of sensation to the other. In nervous dyspepsia there may be a modification in the gastric chemistry or the sensation of the stomach may be involved. Clinically, this is best studied in hysterical anorexia. Assimilation appears to improve when hunger returns, and the feeling of hunger reappears only with the restoration of the sensation of the stomach. The anæsthesia may involve only the superficial parts of the mucous membrane, or penetrate deeper when the digestive troubles are more marked. The author refers to a superficial cutaneous anæsthesia corresponding to the region of the stomach. If the mechanical functions are also involved there may be gastric atony. The same condition of the stomach is noted in melancholia and hypochondriasis. When the treatment is directed to the nervous system these cases improve rapidly without any special regulation of diet.

Insanity in the Medical Profession.—It is not scientifically unwarrantable or unreasonable, from a common-sense point of view, to maintain that the doctor should be judged by the effect his physic has upon himself, and the parson by the character which his religion produces in himself. We ought to admit that an unhealthy medical man is an evidence of unsoundness either in the medical theories of the times, or in the use to which he himself puts them. (*The Hospital.*) This is but fair, and if it be considered rather a transcendental position to take up at the present moment, one can hardly doubt that it will be regarded as a common-

place in the more cultured and rational times which lie in the womb of the centuries that are before us. Looking at certain aspects of medical insanity from the stand-point of high mental detachment, we cannot feel altogether happy at the figure cut by our profession in the lunacy returns of recent years. Lunacy varies with callings, as the recent and previous reports of the commissioners amply prove. Theoretically, there ought to be proportionately fewer lunatics among doctors than among any other class, because doctors know so well the causes and the means of prevention of lunacy. But what are the facts? The facts are that the medical profession ranks higher in the production of lunatics than all other classes except two. Costermongers and pedlers rank highest of all, and then follow woolstaplers and cloth merchants. The very next in order are physicians, surgeons, and general practitioners. The actual figures are even more striking than the bald statement of the fact. Thus, in every thousand costermongers and pedlers there were 20.1 lunatics in the quinquennium ending with 1893. In the same quinquennium there were 18.2 lunatics among woolstaplers and cloth merchants, and 15.8 among physicians, surgeons, and general practitioners. In marked contrast to these damaging figures are the figures relating to railway laborers, navvies, and miners. Those sturdy sons of toil only furnished 4.4 of their numbers to the ranks of lunacy in the quinquennium. We hold that as science advances, especially medical science, lunacy should diminish, not increase; and that the sanest and soundest of all classes should be doctors, whose business is "health." So far the facts are against us. But if we are to continue in the front ranks of practical science we must, without delay, find some means of so conducting our own profession as to at least preserve our sanity as well as our health and life. "Physician, heal thyself!" is a very significant dictum indeed.

A Severe Case.—Two weeks ago I was summoned to the bedside of Djoahnne Sdtleometzhler. The involute and labyrinthinate tangle of his symptoms made me suspect at first that he had absorbed his own name. But further examination convinced me that he was the victim of typhomalariopneumophthisicotrychinotetanoataxionephreticosplenitis. Owing to the ubiquity of pathogenic bacilli, antiseptics are always indicated, so I exhibited calcium betanaphtholalphamononosulphonate. As the patient suffered from severe non-localized pain I gave orthooxyethylanamonobenzoylamidoquinoline combined with salicylaldehydmethylphenylhydrazine. For his insomnia I gave trichloraldehydphenyldimethylpyrazolene.

His wife asked me what ailed him, and what I was giving him. I told her, and she said "yes," and turned very pale.

Upon examining him on the next morning I became convinced that the vital forces had misconstrued the remedies, and that a congerie of retro-absorptions had resulted. I then wrote out the following prescription:

> Tetrahydrobetanaphtholamine,
> Sodium thioparatoluidinesulphonate,
> Orthosulphamidobenzoic anhydride,
> Amidoacetoparaphenetidine..... ...āā ʒ j.
> M. Sig.: A teaspoonful every hour.

When the wife presented the prescription to the druggist he instantly dropped dead! The patient is up and about, but something is wrong with his Broca's convolution—he mutters in a multi-syllabic lingo that is intelligible only to modern pharmacal chemists. I am in hiding where the spiral melody of the woodbine that twineth blendeth ever sweet, low, soothing, murmurous quadrisyllabic rhythmic rune of the gentle polygonum punctatum.—*Medical Gleaner.*

Chyle Cysts of the Mesentery.—Dr. W. H. Wenning says that the origin of these cysts is very uncertain. In some instances undoubtedly rupture of a lymphatic, in consequence of an accident or unusual exertion, may lead to the formation of a cyst. Here, in all probability, the fluid effused between the layers of the mesentery causes some irritation and the formation continues to separate the layers from each other. In other instances a rupture may lead to effusion of chyle into the free abdominal cavity. Single cysts might very easily arise in the first-mentioned manner. When there are multiple cysts, however, the origin is more probably due to stenosis of the thoracic duct. Mendes de Leon thinks that, although a stricture of this nature might cause widening at the bottom of the duct, it does not sufficiently explain the formation of a cyst. Besides this, in cases of stenosis, collateral channels for the conveyance of chyle into the blood have been observed. Virchow, Rokitansky, and Kilian have demonstrated the fact that the entire closure of the thoracic duct may give rise to considerable enlargement and crowding up of the chyle vessels. From the nature of the conditions found in my case I am inclined to believe that stenosis and obliteration of the thoracic duct was the cause of the formation of these numerous cysts. Drs. Jones and Cleveland, who made an autopsy immediately after death, were unable to find the thoracic duct. There were no cysts, in the true sense of the word, if we look upon the sac as an adventitious structure, for the chyle seemed to be surrounded by the walls of the mesentery alone. When this membrane was pierced, or, as I have shown above, simply touched, it would collapse. There was, however, evidence of considerable inflammation of the serous membrane.—*Lancet-Clinic.*

Honey in Erysipelas.—Dr. C. E. Hayward, of Cropsey, Ill., writes: "Several years ago, while treating some bad cases of erysipelas, a lady asked me why I did not use the remedy they used in Montana. I asked her what that was; she said honey. I did use it and found it very effective, and since then have used it in every case of erysipelas on any part of the body. My first treatment is the external application of honey. I shave the head and face if necessary, spread the honey thickly on cloth, cut holes for the eyes if the face is the part affected, and change the application every three or four hours. I have never had it fail to relieve the pain, heart swelling, and nausea, and to shorten very much the attack. I also give internally the usual remedies for reducing the fever and stimulating the emunctories. Three or four days usually suffice to bring about convalescence under this treatment. I could report numerous cases, but would rather every physician would give it a trial, and I am sure he would find a practical addition to his armamentarium."

An Anti-vivisectionist and the Queen of Italy.—While the king and queen of Italy were returning from some ceremony in connection with the celebration of the occupation of Rome, an officer of the Sicilian infantry tried to mount the steps of the royal carriage, at the same time addressing some words to the queen. It was thought that he was appealing for amnesty for the leaders of the Sicilian riots, whom the king had refused to pardon. The officer was arrested and taken to the barracks, where he was closely questioned and declared himself to be an anti-vivisectionist, saying that his sole object in addressing the queen was to beg her to use her influence in prohibiting vivisection. The man was an epileptic.

In Pre-vaccination Days.—A contemporary points out that at the time of the announcement of vaccination by Jenner, small pox caused more than one-tenth of all the deaths of the human race. It may be added that 50,000,000 people died in Europe from small-pox during the eighteenth century. In the sixteenth century the disease appeared in Mexico, and 3,500,000 of the population yielded up their lives in a few years, leaving some provinces almost depopulated. In 1707, in Iceland, 28,000 died in one year, the entire popula-

tion being but 50,000. Seventy per cent. of the people of Greenland died of small-pox in 1734. Macaulay, the historian, observed that the disease was always present, filling the churchyards with corpses, and leaving on those whose lives it spared the hideous traces of its virulence. "If a modern traveller," said one observer, "could be transported to London in the early part of the present century, no peculiarities of architecture, dress, or behavior would be so conspicuous as the enormous number of pock-marked faces he would encounter at every turn." Neither high nor low, rich nor poor, escaped the ravages of small-pox in the pre-vaccination days.—*The Medical Press.*

Literature for Malingerers.—The Rev. Harry Jones tells a story drawn from Portland Prison which is worth reproducing. On going into the library Mr. Jones asked what were the favorite books of the prisoners, and was told, to his surprise, that Buchan's "Domestic Medicine" was more frequently asked for than any other. As there was a surgeon always ready to attend to the ailments of the convicts, the reason for this searching after medical knowledge was difficult to find; but he afterward learned that the description of the symptoms of illness was carefully studied by the inmates of the prison as a scientific guide in the shamming of sickness. A successful malingerer was relieved of his tasks, and obtained the coveted idle time on sick leave.—*British Medical Journal.*

The Rights of Inebriates.—The report of the Scottish Departmental Committee appointed to inquire as to the further legislation necessary to deal with habitual inebriates, holds that they should be regarded as wholly irresponsible. It denies the inebriate's right to administer his property, says he ought not to be allowed to discipline his family, and recommends legislation for him based upon the assumption that he is a lunatic who ought to be placed under restraint, whether he likes it or not. The report classes the victims of opium and other drugs as habitual drunkards, and proposes to give their relatives the power of putting them under restraint. Gold-cures and other alleged specifics are summarily denounced, and their use will be prohibited if the recommendation of the committee be accepted and made a law by Parliament.

Dr. Kitasato is not only the most brilliant scientific investigator in Japan, but one of the most original biologists of the present day of any nation. He worked for many years with Koch at Berlin; and last year, when the plague was devastating Hong Kong, he and Dr. Aoyana discovered the bacterial cause of the plague, and were thereby instrumental in arresting its ravages. He has been extremely successful in carrying out the antitoxin treatment of diphtheria, and out of 34 cases treated by him 31 have recovered. He is at present engaged in carrying out a series of experiments on leprosy with the most satisfactory results. If it is a fact that Dr. Kitasato is on the road to discovering not only the cause, but the cure, of leprosy, he will confer an immense benefit on a long-suffering section of the human race. Japan has always been celebrated for generously acknowledging the services of her men of genius in art and literature, and it is gratifying to learn that Dr. Kitasato's discoveries are looked upon as contributing to the national glory, and that the government has unanimously voted him a sum of money to be devoted to the laboratory superintended by him.—*British Medical Journal.*

Circulatory Lesions in Influenza.—Those of the profession who have seen any considerable number of cases of influenza cannot fail to have been struck with the comparative frequency of alarming cardiac complications, often occurring during convalescence. Dr. Cathomas refers to these circulatory lesions, and mentions the following varieties met with: Venous thrombosis, due to phlebitis, four cases of arterial embolism, all fatal, and involving respectively the popliteal, femoral, brachial, and Sylvian arteries. Arterio-thrombosis occurred in seven cases, exclusive of several in which the Sylvian artery was involved. One patient, aged sixty-four, in hospital for extensive eczema, developed influenza and was seized, during the attack, with difficulty of breathing and later with severe pain in the right arm; the axillary artery was obstructed and no pulse could be felt in the right radial artery. After death an adherent clot was found in the axillary artery, and a second one in the aorta at the origin of the innominate. In conclusion, the author is of opinion that vascular obstruction may occur in influenza as in other infective diseases; and that it may be due to embolism of arteries or veins. Arterio-thrombosis is, happily, a rare complication of influenza, and may begin suddenly like embolism, while the differential diagnosis between embolism and thrombosis may be very difficult.—*Medical Times and Gazette.*

Water-borne Cholera.—In the Annual Report of the Chemical Examiner and Bacteriologist to the Government of India for 1894, Dr. Hankin refers to a remarkable instance of exemption of one company in a regiment suffering from cholera. The East Lancashire Regiment consisted of companies A, C, E, F, G, H. When the cholera broke out in the cantonments the regiment was transferred to the Kokrail Cholera Camp. Throughout the epidemic the E company remained immune from attack, though the conditions of life were identical with those of other companies, and their barracks were almost surrounded by those of companies who suffered severely from cholera. At first no possible explanation of this escape of one company could be found. "On cross-examining the color-sergeant of this company," says Dr. Hankin, "the mystery at first seemed to deepen, for he roundly asserted that the men of his company had exactly the same supplies of food and water as the men of other companies. But on his being pressed as to how he knew that the water-supply was the same as that of other companies he replied that he ought to know, if anybody, as *he boiled it himself!* It is needless to say that on making inquiries we found that this sanitary precaution had not been taken by the color-sergeants of other companies."

"Successful Cancer Institute."—The following curious reading notice appeared recently in the editorial columns of a medical contemporary: "From several reports that we have seen recently in our exchanges it seems that Dr. ——, who has an institute at ——, is having remarkable success in the treatment of cancer and malignant growths. He does not resort to knife or other surgical means, but treats entirely locally and constitutionally."

The Cocada is a measure of distance employed by the Peruvian Indians. It is the distance that an Indian cargo-bearer can walk under the stimulating effect of the coca-leaf. He finds that the nervous excitation begins in eight to ten minutes after introducing a fresh quid of leaves into the mouth, and lasts from thirty-five to forty minutes. In this time the Indian will pass over three kilometres on a level road, and two kilometres on ascending ground. At the end of each cocada the Indian stops to rest and regale himself with a fresh chew of coca. Along the Peruvian highways are definite resting-places, established by this custom, also called cocadas.

Ocular Headaches.—Dr. Landman describes the characters and peculiarities of the forms of headache which depend upon uncorrected errors of refraction. Migraine is rarely caused by such errors, even when it accompanies them, and the headaches caused by ocular defects are usually continuous. They are more frequent in women than in men, and can generally be localized, a diffused, continuous headache being usu-

A PRELIMINARY REPORT ON THE USE OF OXYGEN GAS WITH ETHER FOR ANÆSTHESIA.

BY CARTER S. COLE, M.D.,

INSTRUCTOR IN SURGERY, NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL.

In compliance with the solicitations of a number of gentlemen who have seen ether-oxygen anæsthesia, and in order to facilitate the introduction of what seems to promise some interesting and useful advantages in ether narcosis, by giving the methods which have so far proved successful and satisfactory in our own hands, I am led to offer this preliminary report on the observations made thus far in a very small number of cases.

The idea of employing oxygen was suggested by Mr. J. Preston Carson, a chemist, who had never seen an ether narcosis. The occasion arose a short time since when he heard a friend speak of the "bluing" that had attended an etherization he had witnessed. The details of its use have been worked out independently by Dr. Markoe and myself. Dr. Francis H. Markoe was approached on the subject and consented to give the matter a trial. It was after the latter had used ether with oxygen in three cases, none of which I saw, that Mr. Carson mentioned the matter to me and asked me to experiment on similar lines. This I readily agreed to do, the first thing that was necessary being some proper apparatus for the administration; and to the task of devising the same I immediately applied myself, with the result herein related.

The cone is a simple tin box (Fig. 1), shaped like a coffee can. In the middle of the top a tin tube three inches long is obliquely inserted, half remaining outside. Two rubber tubes leave the bottle, four-fifths full of ether, one of which fits on the

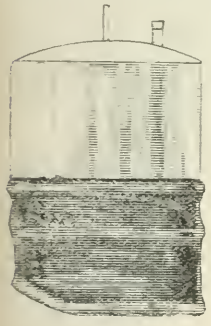

FIG. 1.

FIG. 2.

FIG. 3.

tube in the top of the cone, the other on the oxygen tank. The bottle used has been the "wash" bottle ordinarily employed in giving oxygen gas. An additional opening in the top of the cone which is stoppered by a cork provides for the addition of ether without removing the cone from the face. A perforated platform (Fig. 2) held in place by a removable wire frame (Fig. 3) keeps the gauze and cotton away from the patient's mouth, and a rubber mouthpiece that fits the cone and the patient's face completes the apparatus (Fig. 4). The method first tried was to pass the oxygen through the regular wash bottle, then through the ether itself in another bottle, and thence through a tube to the cone, into which gauze and cotton moistened with ether had been placed. Later the wash bottle was omitted and the tube run from the oxygen tank to the bottle of ether, and the other tube direct to the cone, the gauze and cotton still being kept in the cone. Next the gauze and cotton were left out of the cone and the oxygenized ether passed into the

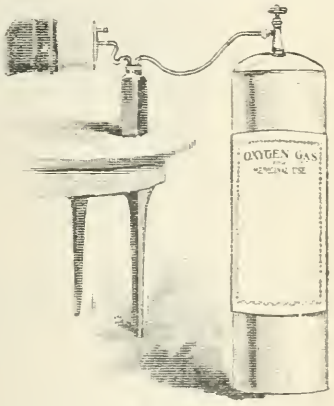

FIG. 4.

cone. In some cases ether was added several times to the gauze in the cone during the anæsthesia; in some none was added. The history of each case gives the details of the variations of methods.

The amount of gas used has probably averaged about a gallon a minute, although it has been impossible to secure the gauge for a number of the cases. The amount of ether used has for an adult averaged about six ounces an hour, and half this quantity for a child. In the case of one child less than three ounces of ether was used for over an hour's etherization (Case IX.). In the case of one man (Case VIII.) less than seven ounces for an hour and a half's etherization.

The longest time for complete anæsthesia in any of my own cases has been fifteen minutes; the shortest a little less than three minutes. The time of recovery has been from fifteen to fifty minutes. Salivation that necessitated a cleansing out of the pharynx has occurred in only one case. Vomiting has not been serious or troublesome in any cases, and in the large majority not even nausea has attended the etherization or the recovery. The effect of increasing the flow of oxygen has been to increase the rapidity of the heart's action and *vice versa*. Respiration has been easy and comfortable, and no struggling nor suffocation has been present. The stage of excitement has been moderate and never troublesome. The color has been uniformly excellent, and not in a single instance has any "bluing" been observed. In the cases in which the temperature has been taken no change has been noted. The largest amount of ether used in any one case has been eight ounces (Case IV.); the smallest less than three ounces for an hour's narcosis.

These then are the facts that have been thus far observed. If each operator will compare the amount of ether used, the time required for narcosis, the frequent absence of suffocating, salivation, struggling, nausea, and vomiting with the conditions that now attend his etherization, he will then be able to draw a conclusion as to the value of the method.

For hospital work a slight increase in the cost as compared with regular ether narcosis may be an important factor in delaying the routine use of such a combination; if the apparent advantages obtain in the experience of others it will be difficult to administer ether to private patients without oxygen. At least it will take but a short time for others to test the matter, and the results of their experience will be of great service, whatever be the outcome.

I subjoin a report of the cases in which I have so far been enabled, by the courtesy of the gentlemen named, to experiment with the method. Dr. Markoe has kindly furnished through one of his house-staff at St. Luke's Hospital, Dr. Squier, a record of his cases to be published with my own, and they are also given.

These then are the paraphernalia: a pure oxygen and a good ether. A tube not more than two feet, leading from the cone to the bottle of ether, and another from the same, as long or short as may be desirable, leading to the tank of oxygen.

A cone that receives and retains the vapor and that fits fairly snugly over patient's face, and so arranged that at a little distance from patient's mouth gauze or cotton or both can be retained, moistened with ether; that ether can be added if necessary without removing the cone, and yet it is not difficult to produce the anæsthesia with only the oxygenized ether, and it is probable that the gauze and cotton will be abandoned. In this report I have endeavored to confine myself to facts—not to offer opinions. In a fuller report, later, I hope to be able to harmonize with the facts the explanation of the same.

Case I.—Dr. Tull, Cancer Hospital. Female, aged about forty, weight about 150 pounds; amputation of cervix. Etherization begun at 9 A.M.; primary anæsthesia, 9.04; full anæsthesia, 9.08; operation begun, 9.13; operation completed, 9.35. Ether used, four ounces; oxygen, twenty-five gallons. No struggling, no suffocation, no gagging or vomiting, except when patient was being wheeled out of the room, then a mouthful of fluid. Recovery without vomiting, without nausea, without headache, in thirty minutes. Color excellent throughout; pulse increased or decreased, by a corresponding use of oxygen; blood noticeably fresh and bright throughout whole operation. Temperature unaffected. Anæsthesia profound; no anæsthetic added to cone or bottle. Gauze used in cone, and wash bottle used.

Case II.—Dr. Tull, Cancer Hospital. Female, aged about thirty, weight about 140 pounds; lacerated cervix. Etherization begun at 9.48 A.M.; primary anæsthesia, 9.50; complete anæsthesia, 9.52; operation begun, 9.58; operation completed, 10.45. Ether, five ounces; oxygen, thirty gallons. Anæsthesia complete throughout. Water was siphoned into ether bottle at outset, but did not seem to influence unfavorably the method of administration. No ether was added to cone or bottle. No struggling, nor nausea, nor frothing. Recovery in thirty minutes, without nausea, headache, or vomiting. Cone not removed from beginning to end of anæsthesia. No vomiting at any time. Color pure throughout. Gauze in cone and wash bottle used.

Case III.—Dr. Cole, Post-Graduate Hospital. Boy, twelve years of age; weight, 80 pounds; circumcision. Objected to being anæsthetized, and struggled at outset. Primary anæsthesia inside of two minutes; operation begun. Complete anæsthesia inside of four minutes, although patient did not remain fully anæsthetized. Operation lasted about fifteen minutes; recovery took as much more. Some nausea, but no vomiting; patient within an hour or a little more took food. Four ounces of ether used. Wash bottle used; no gauze used in cone.

Case IV.—Dr. Guiteras, Columbus Hospital. Man, about forty-five years of age; weight, about 220 pounds. Displaced testicle. A big truckman, a difficult subject for ether anæsthesia. Complained for two or three minutes of feeling of suffocation, though continued breathing without trouble. Primary anæsthesia in nine minutes; full anæsthesia in thirteen minutes; operation lasted one hour and fifteen minutes. Eight ounces of ether used. Gauze in cone and wash bottle used. Ether added to cone several times during anæsthesia.

Case V.—Dr. Cole, Post-Graduate Hospital. Child, male, aged twenty-six months; hydrocele cord. Primary anæsthesia, two minutes; complete anæsthesia, four minutes; duration, thirty minutes. Ether used, two ounces. Usual fright at beginning anæsthetic, otherwise quiet throughout. Cone not kept constantly over face. Vomited a few minutes after operation was completed, but not again. Recovery in about twenty minutes. Oxygen passed through ether directly, and no gauze used in cone. Wash bottle discontinued from this case through the series.

Case VI.—Dr. A. M. Phelps, Post-Graduate Hospital. Woman, aged about thirty-five; weight, 175 pounds; ununited fracture of both bones of forearm. Anæsthesia begun, 4.30 P.M.; primary anæsthesia, 4.38; full anæsthesia, 4.42; anæsthetic stopped, 5.35. Ether, seven ounces. Patient said at previous operation she had taken three cans of ether. Went under nicely, without struggling or suffocation or vomiting. While being transferred to operating-table she vomited mucus, and again once or twice during operation when cone had been removed a few minutes. No wash bottle used, but gauze saturated with ether put in cone; refreshed two or three times during operation. Anæsthesia so profound that cone was kept off face about a fourth of the time and oxygen stopped. Color was always fresh and excellent, even in deepest anæsthesia. Patient conscious and able to speak distinctly in twenty minutes after cone was removed. Pure oxygen was given for three or four minutes after ether was stopped.

Case VII.—Dr. Dowd, Cancer Hospital. Male, weight about 150 pounds. Necrosis rib. Anæsthesia begun, 2.46 P.M.; primary anæsthesia, 2.53; complete anæsthesia, 2.57; operation begun, 3.02; anæsthetic discontinued, 3.27; patient conscious, 3.35. Ether, five and a half ounces. No vomiting nor struggling. Considerable accumulation of mucus during anæsthesia, necessitating removal of cone and cleaning out of fauces. Pure oxygen given for four or five minutes after anæsthetic was discontinued. At previous etherization (several months before) patient suffered considerably from effects of ether, and took a large quantity of the anæsthetic. Later report from patient that only slight nausea and no vomiting followed anæsthesia, and recovery was in a third of the time as compared with the previous anæsthetization. Gauze used in cone, but no wash bottle.

Case VIII.—Dr. Willy Meyer, German Hospital. Man; gastro-enterostomy for malignant growth. Primary anæsthesia in six minutes; complete in twelve minutes. Anæsthetic given carefully and not pushed. Patient under anæsthesia one hour and a half; six and a half ounces of ether used; absolutely no struggling; no vomiting; no gagging; and not once did mucus or saliva have to be wiped off his mouth. Color and pulse excellent throughout. Recovery in forty minutes, without vomiting or distress. Gauze used in cone. Ether added several times during operation, about a drachm each time.

Case IX.—Dr. Willy Meyer, German Hospital. Child; sarcoma of kidney. Primary anæsthesia not noted, but full anæsthesia in three minutes. Anæsthetic administered one hour and five minutes, no gauze

in cone, and total ether used two and one-half ounces. Color excellent, no salivation, gagging, or vomiting.

Case X.—Dr. Cole, Post-Graduate Hospital. Man; epithelioma, floor of mouth. In anticipation of a difficulty in deglutition, I determined to use no gauze and cotton in the cone, in order to reduce as much as possible the saliva to be swallowed, and to give the minimum of trouble in respiration. Primary anæsthesia was quiet and easy, but secondary anæsthesia did not follow in a reasonable time; no gauze or cotton moistened with ether were put in the cone. My reasoning as to interference, of which the physicians present were advised at the outset, proved soon to have been well founded; and the increased irritation from the ether produced some increase in saliva and secretions, which, instead of being swallowed, accumulated and interfered materially with respiration; so that the anæsthetic was discontinued, and the operation rapidly done under partial anæsthesia. Strange to say, even when respiration was exceedingly imperfect, the color remained good; and it was with considerable satisfaction, even in the face of my first partial failure with ether-oxygen anæsthesia, that I reflected how fortunate for the patient that ether alone had not been essayed. A later conversation with the patient developed the fact that he suffered no pain, and was not aware that anything had been done; in short his anæsthesia, which appeared very imperfect, was at least attended by unconsciousness of pain during the operation. Only three ounces of ether were used; no nausea nor vomiting.

Fig. 5.

Case XI.—Dr. Bryant, Bellevue Hospital. Woman, about fifty years of age; weight about 165 pounds. Tumor of breast; anæsthesia primary in eight minutes; secondary in fifteen minutes; anæsthetic administered for fifty minutes; four ounces of ether given. Patient came out in about fifteen minutes. Was restive during early part of operation, but absolutely passive the remainder. Gauze and cotton moistened with ether used in cone; wash bottle has been abandoned for several cases. Recovery without vomiting, and anæsthesia not accompanied by gagging or salivation. Ether added to gauze in cone several times.

It is by the courtesy of Dr. Francis H. Markoe that the following cases in which ether with oxygen has been employed are reported.

The method of administration has consisted in passing oxygen from a cylinder through two wash bottles, the first containing water, the second ether, into a cone, the cone being so arranged that ether may be added directly to it if necessary.

While it is to be regretted that, the method still being in its infancy, more definite results cannot be furnished, yet the majority of cases upon which it has been used have shown: 1. An absence of the so-called stage of excitement. 2. No cyanosis nor respiratory disturbances during anæsthesia. 3. A tendency to regain consciousness more quickly when etherization is discontinued than after the usual methods. 4. No nausea or vomiting subsequent to etherization. 5. The amount of ether consumed to be considerably less than formerly.

Case I.—Female, aged fifty-seven. Diagnosis, carcinoma of stomach. Operation, exploratory cœliotomy. Patient greatly emaciated; lungs, negative; heart, action very feeble; systolic murmur of pulmonic area; ether and oxygen administered slowly; no attempt at rapid anæsthetization; no primary laryngeal spasm or period of excitement.

Patient's pulse, respiration, and color remained excellent until middle of operation, when ether was given alone. Almost immediately the pulse and respiration became very rapid, and patient grew cyanotic.

On resuming oxygen, patient's condition improved at once and remained so until close of operation. After etherization there was no nausea or vomiting for twenty-four hours. This is interesting from the fact that before operation the patient vomited every two or three hours, and that nothing was done at time of operation to alleviate local condition, the walls of the stomach being so extensively involved that gastro-intestinal anastomosis was impossible.

Case II.—Female, aged fifty. Stout, plethoric patient; heart and lungs negative. Operation for lacerated perineum, extensive rectocele, and hemorrhoids; patient fully anæsthetized in four minutes; etherization lasted two and one-half hours, during which time pulse and respiration continued the same as before operation. There was no stage of excitement or after-gastric disturbance.

Case III.—Male, aged about fifty-seven. Diagnosis, enlarged prostate. Operation, castration. Patient fairly well nourished. Heart, systolic murmur over apex, transmitted to left. Lungs, emphysematous. Some very slight struggling at commencement of anæsthesia. Color of patient during operation ruddy, although the anæsthetic was clouded. Respiration

normal. Recovered from ether without nausea or vomiting, and was fully conscious in twenty-five minutes.

Case IV.— Female, aged forty-seven. Operation, excision of irritable urethral carbuncle. Patient's physical condition very poor. Well-marked tubercular changes at both apices. Heart negative.

In this case patient succumbed to anæsthetic as if simply going to sleep. There was no disturbance of respiration during operation, and no cyanosis. Unpleasant after-effects absent.

Case V.—Boy, aged about thirteen. Diagnosis, tubercular knee-joint. Operation, incision and drainage. Patient very poorly nourished. Heart, systolic murmur heard along left border of sternum, also over pulmonic area. Lungs, negative. Pulse, rapid, poor force, regular. Anæsthesia commenced by use of ether alone. Primary stage of excitement present. After fifteen minutes of etherization patient's pulse became very weak, rapid, and irregular. He lost all color and the breathing was bad. Oxygen and ether was now substituted for ether. In a short time the pulse had improved in force (although it remained rapid). Color returned to patient, and breathing regained more of its normal character. No nausea nor vomiting followed administration of the anæsthetic. Other stimulation than the oxygen was not employed when patient's condition was precarious.

Case VI.— Female, aged forty-three. Diagnosis, adeno-fibro-sarcoma of breast. Operation, excision of breast and axillary contents. Patient in good physical condition ; heart and lungs, negative ; anæsthetized readily. No excitement. Pulse regular throughout operation. Blood never lost its bright arterial hue. Twelve hours after operation patient vomited once, but this after taking some brandy and milk. There was no feeling of nausea directly following etherization.

Case VII.—Male, aged twenty. Diagnosis, varicocele. Operation, excision. Patient strong and robust ; heart, systolic murmur over apex ; action irregular ; lungs, negative. Marked alcoholic habit. Patient took anæsthetic very easily ; no stage of excitation. Complete anæsthesia in six minutes. Respiration and circulation very good during operation. It took rather longer than usual for patient to regain consciousness (fifty minutes), and both nausea and vomiting occurred after discontinuance of anæsthetic.

Case VIII.—Male, aged twenty seven. Diagnosis, tubercular arthritis of shoulder-joint. Operation, atypical resection. Patient fairly well nourished. Lungs, tubercular signs at left apex well advanced. Heart, negative. Period of excitement present. Patient slightly cyanotic during anæsthesia. Nausea and vomiting present after etherization. Patient conscious after one hour.

Case IX.—Male, aged fifty-three. Diagnosis, cystitis. Pyelo-nephritis. Operation, median perineal cystotomy. Patient intensely emaciated ; condition almost uræmic. Heart and lungs, negative ; pulse and respiration, rapid and irregular. Only five minutes required to anæsthetize patient. Patient in such a weak state that inhalations of pure oxygen were given alternately with the oxygen and ether. By these means he stood the anæsthetic well, although he looked to be in extremis throughout the operation. No nausea nor vomiting subsequent to etherization.

Case X.—Male, aged about fifty years. Diagnosis, cellulitis of neck. Operation, incision and drainage. Patient in good condition ; heart and lungs, negative ; breathing difficult on account of abscess in neck pressing against trachea. Anæsthesia produced slowly from the above fact. Slight excitement ; no cyanosis, even though trachea was obstructed. Pulse regular, good force during operation. Recovered from ether without gastric irritability.

The intense thirst so often present after etherization has been greatly moderated in every instance, and the feeling of suffocation less marked. Albumen and casts have appeared in the urine with about the same percentage of frequency as when ether is administered by other methods. The atmosphere of the operating room has remained almost free from the odor of ether.

In concluding this report I may add that it will be interesting to experiment with compressed air similarly used, and possibly other gases ; but for the present we will content ourselves with recording the cases and facts as we have observed them, and of submitting the report of Dr. Markoe's cases from Dr. Squier, as we received it. The illustrations are of the simple apparatus which I have devised and used.

101 West Seventy-fourth Street.

THE PROOFS OF PROGRESS.[1]

By GEORGE M. STERNBERG, M.D., LL.D.,

SURGEON-GENERAL UNITED STATES ARMY.

The great obstacle to the advancement of medical science in the past has been respect for authority and the acceptance of theories and supposed facts without submitting them to the test of experimental verification.

The humoral pathology which Galen (born A.D. 130) developed from the previous teachings of Hippocrates controlled medical thought and influenced medical practice for 1500 years. But we have been emancipated from the trammels of theory and superstition, and the medicine of to-day is largely based upon exact observation and experimental demonstration. In other words, we may now properly speak of medical science, for, while our knowledge in many directions is far from being complete, it is founded upon a scientific basis of observation and experiment and is being rapidly extended by scientific methods.

The unthinking and unscientific are very ready to believe that not knowing is due to ignorance on the part of the individual, when in reality it is the brief statement by a well-informed man that the matter referred to has not been determined, and that no one can give the desired information. Under the same circumstances an ignoramus or a charlatan, instead of confessing ignorance, would perhaps gain great credit by a positive assertion with reference to a matter of which he could not possibly know anything. But science teaches that a confession of ignorance is the first step toward the attainment of knowledge. When the anxious mother says : " Doctor, is it diphtheria ? " and receives the answer " I don't know ; there is a somewhat suspicious deposit upon the tonsils, and I will at once make a microscopical examination and a culture which will enable me to determine the matter within twenty-four hours," she will probably not be as well satisfied with her medical attendant when she receives the assurance after such an examination, that " it is not diphtheria," as she would have been with the non-scientific doctor, who claims to recognize diphtheria at a glance, announces his diagnosis at once, and " cures " the patient within a day or two. The latter has earned the mother's lasting gratitude, and she will not fail to recommend him to her friends as competent to cure any ailment to which humanity is liable. But our scientific doctor will make his way in the end. He will enjoy the confidence of his fellow-practitioners, and his patients will learn after a time that when he says he knows a certain thing he really knows it, and when he says he don't know, he will do his best to find out, if the question can be solved by reference to the medical works in his library, or by an experimental investigation which it is practicable for him to make personally, or which can be made for him in a laboratory devoted to scientific research. He does not make a snap judgment, but waits until all the evidence is in. It is evident that the opinion of a man of this type is of value. His diagnosis, his prognosis, and his advice

[1] Extracts from an address delivered at the Georgetown Medical College, September 1, 1895.

as to treatment are based upon a careful investigation of the case in hand, a full knowledge of the literature relating to similar cases, and a precise appreciation of the indications to be met by the treatment prescribed.

The conservatism which makes the scientific physician willing to confess ignorance is a very different conservatism from that of the pretentious charlatan and quack, who gives an emphatic denial to facts that are well established upon evidence with which he is not familiar, or which his intellect is not capable of appreciating. I have protested against calling the graduates of our leading medical colleges "old-school" doctors, but it must be admitted that there are still some very old-school doctors among the former graduates of regular medical colleges. In the ranks of the medical profession, as elsewhere, there are men who have been left behind in the rapid development of our knowledge, and who protest against the acceptance of facts which have been established by the most unimpeachable experimental evidence. By such protest they simply reveal their own ignorance. But as their opinions are often stated in good and forcible English, other persons, equally ignorant of the evidence, frequently accept them, or quote the old saying—"When doctors disagree, who shall decide?"

As examples of this conservatism of ignorance I submit the following quotations from two recently published papers, having the names of regular graduates in medicine attached to them. In a report to a State Medical Society, signed by a reputable physician, among other conclusions formulated I find the following:

(2.) "That the etiology of infectious diseases is as yet *sub judice*, and that therapeutic methods based upon the assumption that infectious diseases are caused by specific micro-organisms are unscientific."

Another medical writer concludes a popular magazine article as follows:

"We are brought, therefore, to the conclusion inevitably: The germ theory is an assumption of causes, of the existence of which we have no evidence, to account for effects which they by no means explain."

The training which the medical student of the present day receives in the laboratory is essential for other reasons than because of the scientific spirit, which is developed by personal verification of the facts which are recorded in his text-books of chemistry, histology, bacteriology, etc. Not only does this personal verification impress the facts upon his memory, but he obtains that technical skill in the use of instruments and methods which can only be acquired by practice. In the chemical laboratory he learns to detect poisons, to determine the nature of impurities in water or air, to examine urine, etc. His practical course in histology makes him familiar with the use of the microscope and with the minute anatomy of healthy tissues. In the pathological laboratory he learns to recognize the results of different morbid processes and the presence of parasitic micro-organisms in the blood or tissues, to distinguish between malignant and innocent growths, etc. By cultivating the principal pathogenic bacteria and examining them under the microscope, after treatment with various staining agents, he becomes familiar with their biological and morphological characters and is able to recognize them wherever they may be encountered. In short, he obtains a practical knowledge of many things, which it is essential for him to know in order that he may be a skilful physician. The knowledge to be obtained from books, which enables the student to pass a creditable examination, does not make him a chemist, a pathologist, a skilful diagnostician, a surgeon or a physician any more than the knowledge to be obtained by reading books on agriculture makes a man a farmer, or than the study of books on navigation would enable a man without practical experience to take command of a trans-Atlantic steamer. It is in recognition of this fact that the Medical Faculty of the University of Georgetown has, as already stated, decided to extend the hours of instruction "so that more time may be given to practical work in laboratories and hospitals." Every physician of experience will approve of this decision. It is true that but few of the prominent physicians of the present day enjoyed such advantages as it is proposed to give to their successors. It is also true that a majority of these prominent physicians were very imperfectly prepared for the duties and responsibilities of a general practitioner when they received their medical degree. This fact has long been recognized within the ranks of the profession, and it is for this reason that hospital appointments have been so eagerly sought by those having a proper professional ambition. In the hospital the young doctor learns to apply his knowledge and to meet emergencies with composure and professional skill. His books have taught him what to look for, what to listen for, and what to feel for, but practice alone can give him the trained eye, the trained ear, and the *tactus eruditus* of the accomplished physician.

It is in the laboratory that the student acquires deftness in delicate manipulations required in his chemical, histological, and bacteriological studies: here he learns to measure and weigh with accuracy, to appreciate the slight differences in color-reaction, in form or in structure, upon which he must often depend for the recognition of toxic agents, pathogenic germs, or abnormal growths; his eye becomes trained to recognize the malarial plasmodium, the tubercle bacillus, and other micro organisms, which are only revealed to us by the highest powers of the microscope, under proper illumination, and in skilfully mounted preparations; and it is here that conditions are most favorable for the development of that spirit of doubt and inquiry which is so essential for the progress of scientific medicine. Where there is no doubt there will be no investigation. The farmer who accepts the traditional belief that certain seed must be planted in the light of the moon, in order to obtain the best results, would consider it a waste of time to make a comparative experiment. But it is by means of comparative experiments that we arrive at definite conclusions in the laboratory, and the great diversity of opinions with reference to the curative action of drugs is largely due to a failure to apply the same methods in practice. This failure has been partly due to want of appreciation of the necessity for a control-experiment in judging of the results supposed to follow a certain course of treatment, and partly to the difficulty of making such a control-experiment in clinical medicine. The unscientific mind jumps at conclusions that are entirely unjustified by the facts. The warts upon the child's hand are rubbed with a piece of meat which is thrown over the left shoulder, etc., and they subsequently disappear; a horse-chestnut or a potato is carried in the pocket for years and the individual does not suffer from rheumatism during the entire time. The child has a high fever at bed-time, the mother gives it a sugar pill and the next morning the fever has entirely disappeared, and so on *ad infinitum*. *Post hoc ergo propter hoc.* But the man of science asks: What would have happened if the warts had not been rubbed with meat, or saliva, or whatever may have been the particular fetich employed? Would the man have had rheumatism if he had left the horse-chestnut on the tree or the potato in the ground? Would the child's fever have disappeared if the mother had failed to give it the sugar pill? To determine this a comparative experiment is evidently required. Take the case of the child, for example. To determine whether the disappearance of the fever was in fact due to the administration of the sugar pill we should have another exactly similar case—a child of the same age, under similar conditions and suffering from an elevation of temperature due to the same cause. One child should have the pill and the other should have nothing. Even then the result would

not be conclusive. Science demands that the experiment should be repeated several times. There are so many chances that the conditions may not, after all, have been exactly identical. No truly scientific man would venture to announce a fact as established upon the basis of a single successful experiment. And, having in view the fallability of human judgment, the tendency to draw conclusions favorable to the prejudices or desires of the individual, and the frequency with which erroneous conclusions are published upon what appears to be a substantial experimental basis, science demands verification of reported results by two or more independent investigators before finally accepting these results as demonstrated facts. All this is so far away from the ordinary methods of arriving at conclusions, that the conservatism of the scientific physician meets with little sympathy on the part of the general public. The man with a horse-chestnut in his pocket is not only convinced by his individual experience that this is a sovereign cure for rheumatism, but he is apt to resent your non-acceptance of his experiment as conclusive. We, on the other hand, know that medical literature abounds in instances of the ultimate failure of therapeutic agents and methods of treatment, which have for a time been lauded as specific, and have been endorsed by prominent physicians. We are therefore becoming more and more exacting in our demands as regards proof, and as a result medical science is making rapid progress. How great this progress has been is not fully appreciated by the non-medical public.

While we justly pride ourselves upon the rapid development of our knowledge during the last half of the present century, we must not forget that in some directions the foundations of scientific medicine were substantially laid by the illustrious physicians of the past. The time at my disposal will not permit me to give an extended review of the development of medical knowledge, but a brief reference to some of the more important events which have marked this progress will perhaps be useful, as showing the extent of the field and the advantages which the physician of to-day has over his predecessors.

Hippocrates and his illustrious successors, Celsus, Galen, and others, were certainly the peers of modern physicians in their powers of observation, and we are indebted to them for a mass of recorded facts relating to disease, which have been verified and added to by subsequent observers. But observation, in the absence of the instruments and methods of modern science, goes but a short distance in the direction of unveiling truth, and often leads to erroneous conclusions. Observation led the ancient philosophers to believe that the sun goes around the earth, and that water and air are elements. The experimental methods of modern science have revealed to us the constant presence of three elementary gases in the atmosphere, one of which is also a constituent of water, while one—argon—has only just been revealed to us by the researches of Professor Ramsey and Lord Reyleigh. One of the first lessons to be learned by the student of medicine is not to trust implicitly to the evidences of his senses. This is the fundamental error of ignorant persons, and the foundation of demonology and superstitions of all kinds. The eye tells us that water from the well is perfectly pure, but the microscope shows us that it swarms with living organisms. The touch tells us that the patient has a high fever, but the clinical thermometer says no—the sensation received was due to the comparatively low temperature of our own hand at the time of making the observation, etc.

The anatomical knowledge of "the father of medicine" was very imperfect, because it was not obtained by the dissection of the human body. The Greek physicians Herophilus and Erasistratus, of the Alexandrian school of medicine, who lived about 300 B.C., are believed to have been the first to study anatomy in this way, and from that time our knowledge in this essential department of medicine has steadily increased, until at present it is perhaps more nearly complete than in any other branch. The medical student of to-day is expected not only to acquire an accurate knowledge of anatomy in the dissecting room, but he must study the minute anatomy of the tissues by means of the microscope and the methods of investigation, which he will learn in the histological laboratory. He is also expected to have at least an outline knowledge of comparative anatomy, a branch of scientific research which dates back to the time of Aristotle (384 B.C.) and which has been greatly developed during the present century. Our knowledge of minute anatomy has been largely acquired during the past sixty years, as a result of the improvements in the compound microscope made about 1830. The perfecting of this invaluable instrument of research has also led to vast additions to our knowledge in the department of general biology, of which it is important that the medical student should possess at least an outline. A knowledge of the structure and development of lower organisms is justly regarded as a proper introduction to the study of human anatomy and physiology. Embryology, a branch of science which may almost be said to have had its birth in the present century, must not be neglected by the student of medicine. It is true that Galen made observations upon the development of the incubated egg, and that Harvey, in the seventeenth century, made some important observations in the same line of investigation, but the minute and accurate knowledge of the present day depends upon the comparatively recent improvements in the compound microscope just referred to.

Progress in physiology, as in other branches of medical science, has resulted from the application of the experimental method to the problems to be solved. Galen made an important addition to human knowledge when he demonstrated that urine is secreted by the kidneys, a fact which, apparent as it seems to us to be, had not previously been recognized. It was nearly fifteen hundred years later that Harvey (1628) demonstrated the circulation of the blood, a discovery which is justly considered one of the most notable events in the history of medicine. The subsequent explanation of the process of respiration by Lavosier (1783), the experiments upon gastric digestion by Beaumont (1834), and the discovery of the function of the vaso-motor nervous system by Claude Bernard, opened the way to a fertile field of research which is still being vigorously prosecuted in physiological laboratories; and the results attained constitute an essential part of a medical education. The progress of our knowledge of physiology has necessarily been secondary to the advancement of chemistry. Indeed, physics and chemistry constitute the foundation of medical science. We, therefore, place Priestley's discovery of oxygen (1783) among the epoch-making events in the history of medicine. It is due to chemistry that we are able to use the active principles of various drugs of demonstrated value, instead of the crude material—leaf, root, or bark; and the chemists have recently made many valuable additions to the list of approved therapeutic agents—principally from the series of coal-tar products.

The importance of carefully studying the results of morbid processes in the post-mortem room and in the pathological laboratory is now generally recognized, and the medical student will find that since Morgagai (1682–1771) led the way in the study of morbid anatomy, an enormous amount of work has been done in this field of investigation. He will be required to make himself familiar not only with the facts developed, but with the methods of research and the microscopical and gross appearances of tissues, which have undergone the changes due to disease. Important as these studies are, the results obtained, from a practical point of view, are eclipsed by the brilliant discoveries which

have been made during the past twenty years with reference to the etiology of infectious diseases, which to a considerable extent have been prosecuted in laboratories devoted to pathological research. These discoveries, like others heretofore referred to, depend primarily upon the improvements which have been made in the compound microscope, especially in high power objectives and means of illumination; and upon methods of research devised by the pioneers in this field of investigation, among whom the names of the French chemist Pasteur, and the German physician Koch are pre-eminent.

The development of our knowledge relating to the bacteria dates from the controversy relating to spontaneous generation, which was finally settled by the experimental demonstration made by Pasteur (1860), that no development of micro-organisms occurs in organic infusions which have been sterilized by boiling; and that fermentation and putrefaction depend upon the introduction of living germs into such infusions. The distinguished French physician Davaine first demonstrated the etiological relation of a micro-organism of this class to a specific infectious disease. The anthrax bacillus had been seen in the blood of animals dying from this disease by Pollender in 1849, and by Davaine himself in 1851, but it was not until 1863 that the last-named observer felt justified in asserting, as a result of inoculation-experiments, that the bacillus was the essential etiological factor in the production of anthrax.

In 1873 the German physician Obermeyer discovered the spirillum of relapsing fever in the blood of patients suffering from that disease. The typhoid bacillus was discovered by Eberth, and independently by Koch in 1880. The same year the present speaker discovered the pathogenic micrococcus, which is now recognized as the cause of croupous pneumonia. In 1882 Koch published his discovery of the tubercle bacillus. The glanders bacillus was discovered by Loeffler and Shutz in 1882; the bacillus of diphtheria by Loeffler in 1884; the bacillus of tetanus by Nicolaier in the same year. It was also in this eventful year that Koch published the discovery of the cholera spirillum. Since these important discoveries our knowledge of the pathogenic bacteria has rapidly increased, and it is now demonstrated that erysipelas, septicæmia, puerperal fever, wound infections, boils and abscesses, peritonitis, pleurisy, etc., are due to general or local infection with germs of this class.

Evidently the medical student of the present day must be made familiar with these recent additions to our knowledge of disease, and his acquaintance with these microscopic foes of the human race should be of that practical character which can only be obtained in the laboratory.

I have already occupied so much time that I can refer but briefly to the advancement in clinical medicine, which depends largely upon additions to our knowledge already referred to. The use of the stethoscope, the clinical thermometer, the laryngoscope, the ophthalmoscope, and other aids to diagnosis has introduced certainty in place of uncertainty, science in place of guess-work. Our knowledge of the pathogenic bacteria tells us not only where to find them, but how to destroy them when they are accessible to the action of physical or chemical agents. This knowledge has undoubtedly resulted in the saving of thousands of valuable lives. This has been accomplished by means of antiseptic or aseptic methods in surgical and obstetrical practice, and by the intelligent use of disinfectants for the destruction of infectious material, wherever it may be found. As a result of such procedures we have during recent years escaped any devastating epidemic of cholera or yellow fever, although the first-mentioned disease has twice been introduced into the harbor of our principal seaport, and yellow fever prevails annually in the cities of Havana and Vera Cruz, with which we have close commercial relations.

The medical student is expected to prepare himself for continuing the work of his predecessors in preventive medicine, although this work has a constant tendency to diminish the demand for his services. To the credit of our profession be it said that this selfish point of view has never controlled its action, and it is largely to the efforts of physicians that existing laws and regulations have been enacted for the prevention of the extension of infectious diseases, the maintenance of a pure water supply for towns and cities, and general sanitary supervision exercised by local and State boards of health.

The most notable recent additions to our therapeutic resources are the antitoxins of diphtheria and of tetanus, and the use of thyroid extract for the cure of myxœdema. But I cannot dwell upon the possibilities in the way of specific medication, which are suggested by these recent achievements of scientific medicine. Certainly, I have said enough to indicate to the young man who contemplates entering upon the study of medicine, that his best energies will be needed to master all the important details in the various branches to which reference has been made; and to justify the Medical Faculty of the University of Georgetown in extending the hours for instruction and in requiring that students shall take the practical laboratory courses, which have been arranged for, as announced in the recent "Circular of Information" already referred to.

Having attempted to give you some idea of the present status of scientific medicine, I desire briefly to call your attention to certain matters which are extremely discouraging for the truly scientific physician, although he seldom refers to them, and, perhaps wisely, trusts to time and the diffusion of knowledge to remedy the evils to which I shall refer.

Hand in hand with the progress of medical science we see an army of pseudo-scientific quacks who trade upon the imperfect knowledge of the masses, and by plausibly written advertisements convince many, even of the educated classes, that their particular method of treatment is based upon the latest scientific discoveries. A Priestley discovers oxygen; the physiologists show that this gas is essential to life, and that the maintenance of a full degree of vital activity depends upon the possession of healthy lungs of ample capacity and the respiration of pure air; the scientific physician discovers defects in the respiratory apparatus, and under certain circumstances prescribes oxygen for the relief of symptoms resulting from a deficient supply of this life-sustaining gas. But the pseudo-scientist extols oxygen as a cure-all for pulmonary complaints, or invents an apparatus, which may be held in the hand or carried in the pocket, by which oxygen will be absorbed in some mysterious way, and without difficulty obtains numerous certificates as to the marvellous cures effected by his method. A Franklin draws lightning from the clouds; a Galvani shows that an electrical current may be developed by the contact of metals and that such a current causes muscular contraction; and innumerable patient investigators add to our knowledge of electricity. The scientific physician avails himself of this potent agent for the treatment of certain ailments, in which it appears to be indicated, but admits that he meets with many disappointments in his clinical experiments. The pseudo-scientific quack writes, or has written, advertisements in which fact and fiction are so commingled that even educated persons may be deceived, and having aroused interest in the alleged therapeutic value of this mysterious agent offers his electric belt, or finger-ring, made of two metals, or pocket battery, as a sure cure for certain specified ailments; or, if less modest and more certain of the credulity of the public, as a cure for all of the diseases to which man is subject. Again, a Pasteur proves that the disease of sheep and cattle known as

anthrax is due to a microscopic organism found in the blood; an Obermeyer discovers a different micro-organism in the blood of relapsing fever patients, and numerous patient workers in laboratories rapidly add to our knowledge of pathogenic bacteria. Then comes the man with the microbe-killer. He tells you that all diseases are due to germs in the blood and that his fluid kills them without fail. Science has demonstrated that comparatively few of the infectious diseases of man are due to the presence of pathogenic bacteria in the blood, and that the microbe-killer has but little germicidal value; but a credulous public accepts the interested statements which appear to have a scientific basis, and swallows the microbe-killer with impunity, if not with benefit. And so it goes, science establishes the value of thyroid extract for the cure of myxœdema, and immediately the public are called upon to swallow extracts of brain for cerebral troubles; of heart, for cardiac disease, etc. Even the Chinese pulse-doctors obtain a large *clientele* on the Pacific coast. Their solemn looks and pretentious claims impose upon the ignorant, and it is said that educated people not infrequently consult them. It is true that in China, as elsewhere, there are two classes of physicians. Those who are educated and who are familiar with the medical classics of their country, and the itinerant quacks, who are not only ignorant but unprincipled. No doubt, the regular practitioner in China believes in his own pseudo-science. According to a recent author,[1] "the learned Chinese doctor is not ignorant in the sense that he has not studied, as from early youth he has been subjected to a degree of cramming and of learning by rote, such as would discourage and wear out the less patient and less toiling Caucasian. He has been obliged to learn stacks of sacred precepts taken from their most ancient sages; and the admixture of intricate and bewildering astronomy, meteorological signs, and endless physical complication of concurrent signs, appearances and detached disturbances, that he has been compelled to learn by heart, is simply appalling. Anatomy and physiology cut no figure in these studies and they are considered wholly unnecessary, as disease is a matter depending on good or bad vapors, and is either of divine or diabolical origin. In spite of their most elaborate treatises upon the pulse, from which they profess to be able to perform the most skilful diagnosis, they are even unacquainted with the existence of the circulation."

The time at my disposal will only admit of a brief reference to the Chinese theories relating to disease and its treatment. As was the custom among the more enlightened Occidental nations, until a comparatively recent period, their prescriptions often contain twenty or more ingredients, apparently given with a vague idea that one out of the number may prove to be the right remedy. These ingredients are obtained from all imaginable sources and include all kinds of nastiness, in the way of excretions, desiccated animal tissues, etc. With them the color of a medicine is an essential character: red medicines being suitable for diseases of the heart; white, for pulmonary complaints; black, for diseases of the kidneys; green, for those of the liver; and yellow, for those of the stomach. In the use of remedies from the vegetable kingdom the leaves and branches are most appropriate for diseases of the extremities, the bark should be used for skin diseases, the pith for derangements of internal parts of the body, etc.

In conclusion, I desire to emphasize the fact that learning does not enable a man to distinguish between science and pseudo-science. The learned disciples of Confucius in the Orient, and classical scholars of the pre-scientific epoch in Occidental countries, formerly failed to distinguish between the fact of astronomy and the fancies of astrology. And, at the present day, eminence as a classical scholar, or as a theologian, or as a jurist, or as a metaphysician, in the absence of a knowledge of the methods and results of modern scientific investigation, does not enable a man to distinguish between science and pseudo-science in medical practice. This kind of learning is therefore not essential for the physician; but, as we insisted at the outset, he should not enter upon the study of medicine without having at least a thorough knowledge of his own language and of those branches of study pursued in the high schools of our large cities; we now add that a reading knowledge of the French and German will be very desirable, if he wishes to keep entirely *au courant* with the progress of medical science.

[1] Dr. P. C. Remondino, of San Diego, Cal.

A CASE OF EXTENSIVE TRAUMATIC BRAIN LESION WITH VERY MEAGRE OBJECTIVE SYMPTOMS.

By A. HRDLICKA, M.D.,

STATE HOSPITAL, MIDDLETOWN, N. Y.

It is almost inconceivable how, in the light of our present knowledge of brain functions and their localization, extensive brain lesions may exist with objective and even subjective signs of them almost wanting. Can ounces of the most important of tissues be destroyed without it having an effect on the system in general? Should we obey simply our reason and logic, this would appear impossible; it would seem that the deficiency of symptoms is not due to their absence, but rather to their strange and subtile nature, that evades our poor means of investigation. Gross experience, however, and especially such illustrations as the following, would seem to sustain the former conclusion.

The case reported here has been from the first to the last day under my steady, more or less direct, observation; mine was also the post-mortem examination, and these causes, combined with rareness and general interest of the case will, I hope, authorize its somewhat extended report.

The case is that of a young Scotchman, aged twenty-eight, who acquired gonorrhœa, followed by orchitis, lost work on this account, got depressed, and, on July 18, 1894, shot himself. Dr. Swartout, of Port Jervis Hospital, under whose care the suicide was committed, informs me of the following:

W. D—— was admitted to our hospital July 18, 1894, at 10.30 P.M., with a pistol-shot wound of the abdomen and of the head just back of the right ear. He was a coachman at Glen Spey, N. Y., twelve miles distant, and was transferred here in a carriage, having received the wounds the forenoon of the same day. On examining the case we deemed it not a case for operation, dressed the wounds antiseptically, and treated him on the expectant plan, thinking it would be only a few days before he would die. On removing the temporary dressing from the head about one-half ounce of brain matter exuded. He remained in a semi comatose, and at times wandering, condition, until about August 2d or 3d, when he became thoroughly insane, and so noisy that he disturbed the rest of our patients, and on August 4th he was transferred to the Middletown State Hospital. He was thought to have suffered with temporary melancholia before inflicting on himself the wound.

On August 4th the patient was admitted to the Middletown State Hospital in the following condition: Temperature, 98.8° F.; pulse, 90, soft; tongue clean; pupils dilated; bowels and urine normal; appetite fair; heart feeble. No paresis. Would not speak. (Committing certificate speaks of some facial paralysis, which cannot be detected.) Wound, situated in the

right lower part of the abdomen, almost healed: the one behind the ear open and slightly discharging. Bed-sores over sacrum. Acknowledges that he shot himself. Hearing on the right side deficient. The temperature on the second day rose to 100.6° F.; but did not again exceed 100° F. The pulse varied between 60 and 84.

In a general way the patient became very sensitive, and often complains of pain in the head on least motion. At times appears to be in a kind of stupor and does not clearly comprehend then what is said. Sleeps and eats well.

August 10th and 11th.—No discharge from the wound on the head; bed-sores improving; mentally much brighter; anxious to get well.

August 19th.—Wound begun to discharge little thick, yellow pus.

September.—Doing very well; slightly costive.

October 13th.—Mental improvement continuous. Complains occasionally of "clicking" in his head; little hypochondric at times.

October 29th.—Two convulsive attacks, at 10.30 A.M. and 12.5 P.M. respectively. The convulsions came unexpected, and were general in character. After the second the patient slept three hours; no recollection, on waking, of any attack. No disturbance of any of the special senses.

November.—Nothing abnormal.

December 17th.—A convulsion, similar to the two previous, at 3 P. M.; sleep nil night after.

January 1, 1895.—Another convulsive attack this A.M.; fell out of bed during it without warning.

January 5th.—Another fit; nearly kicked off his left big toe-nail.

January 10th, A.M.—Vomited, and had a rapid rise of temperature to 101.2° F., and an almost equally sharp decline to normal the following day.

January 12th. — Coming and going pains in the head.

January 16th.—Head aches all over.

January 21st.—Irritable, unreasonable.

January 31st.—Splitting headache.

February 2d.—Very weak; depressed; refuses to eat: stubborn, fault finding.

February 3d.—A sharp pain in the right temple over the eye.

February 19th.—A bit of triangular bone removed from the wound.

March 1st.—Headache; groaning; sullen; sleepy; did not eat breakfast; complains of continuous pain through the head in the region of the wound; considerable nausea. Hearing on right still deficient.

March 3d.—Headache terrible, shooting, splitting.

March 5th.—Headache continuing; the patient reasonable, desires an operation. His wish was complied with. An exploratory incision was made, and three large fragments of the inner table, all loose and pressing on the brain, were removed. Patient stood the operation very well, and after it slept quietly. His general condition improved markedly, and remained so until the 10th, when he grew again restless and begun to complain of renewed headache. From this day until the 17th his condition was as favorable as could be wished. He had no more convulsions since the operation. Never complained of any disturbance of sight.

March 17th.—Wound in good condition; incision healed by first intention. The patient looks, acts, and talks better than he has for weeks. Says his head feels easy. At 4 P.M., while the wound was being redressed the patient vomited and became temporarily weak and dull. At 8.15 P.M. began suddenly having convulsions, general, almost continuous, but not very severe. Convulsions stopped at 9.30; breathing begun to assume stertorous character; unconsciousness set in; temperature rose to 103½° F.; pulse, 76; respiration, 30; pupils dilated; *exitus lethalis* at 11.55 P.M.

Autopsy, March 18th, 10 A.M. *Inspection.*—Body moderately nourished, symmetrical, face very anæmic. Rigor mortis very marked. Scrotum loosely pending, discolored, brownish. A drop of pus in urethra.

Signs of Injuries.—A pouch-like healed scar on the right side of the abdomen, two inches above the anterior superior spine in McBurney's line. A round with extruding tissues filled opening on the right side in the skull, an inch and a half above the tip of the mastoid process, and two-thirds of an inch behind the junction of the exterior ear with the scalp. From this, leading upward and forward, an irregularly healed cicatrix (incision).

Section.—Scalp thick, well nourished. In the immediate vicinity of the wound and upward, along the incision line, subcutaneous tissues thickened, discolored light brown, and slightly soaked with thick pus. Discoloration of the scalp tissues all over the occiput on the right and below. At the lower edge of the wound, under the skin, is lodged a shell of a bullet. On removing the periosteum the opening in the skull is found to be almost regularly circular, of almost half an

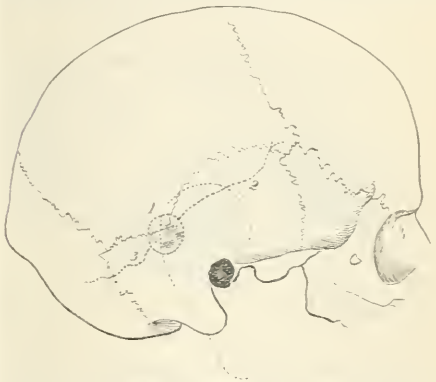

FIG. 1.—1, External wound; 2, anterior fracture; 3, posterior fracture.

inch in diameter. The edges are slightly serrated, but thin and dull. Running upward and forward for two and a half inches is a fracture of the skull, with both ends healed and the middle so open that it admits the tip of the scalpel easily. Running backward and downward, in almost the opposite direction from the first, is a second fracture, all healed, and traceable for about one inch distance. Through the opening itself protrude, like a bunch, some velvety, tough tissues. Skull-cap very thin, but mostly compact. Ethmoidal rostrum very high (three-fourths inch). No adhesions to the bone, no further signs of injury. The opening presents the same characteristic from inside as it did from outside. Dura hyperæmic; through it loom greatly congested vessels of the pia. Meningeal fluids diminished. Adhesions, moderate, along the margin of both hemispheres in the median line, from the first frontal to the first occipital convolutions. Surface of the brain uniformly discolored dull yellow; consistency augmented. Right temporo-sphenoidal lobe soft; when partially lifted up it is found surrounded with a small quantity of pus, which is similar in character to that found on the outside of the skull. Around the wound, to the extent of three inches vertically, and two antero-posteriorly, all the meninges are firmly adherent together and thus to the brain substance, which appears here dark yellow. On trying to extract the brain with these adhered membranes, a light tension induces a rupture in the brain substance of the temporo-sphenoidal lobe, and from this opening wells out about an ounce and a half of thin, greenish, odorless, flatulent pus, and with it another small shell of a bullet. On closer examination

almost the whole temporo-sphenoidal lobe is found destroyed, what is not pus being softened. In the direction of the wound, and slightly upward, the finger detects some hard, irregular, firmly embedded body. The whole encephalon, minus the pus escaped, is found to weigh fifty-six ounces. Base of both brains hyperæmic. Left half of the pons larger than the right.

The brain was taken to the hospital for further examination, which revealed the following: On cutting down to the hard body another, double cavity, as it later proved, was opened, and from it escaped about twelve drachms of thick, also odorless, grass, or rather malachite-green, pus. These cavities occupied the position between the termination of the fissure of Sylvius, gyri supramarginal and angular, and sulcus occipital anterior, and above the sulci temporalis super and occipital lateral; they just reached to the internal capsule in front, and did not communicate with the lateral ventricle. The wound itself was situated in the first temporal convolution, underneath and behind the lower termination of fistula Sylvii, and extended for an inch and a quarter into the brain substance. The course of the wound was filled up with tough connective tissue;

FIG. 2.—Showing location of abscesses.

at its inner termination were lodged, also surrounded by fibrous tissue, four small fragments of the skull, and the lower crushed half of a pistol-bullet, No. 32. Gray matter of the cerebrum was found pale-yellowish, rather thin. Ventricles filled with clear fluid. Puncta vasculosa abundant throughout the white matter. Basal ganglia, medulla, and cerebellum normal.

Thoracic Organs.—Lungs free, congested, especially the left; pleural cavity contains about a pint of sanguinolent, dark, odorless fluid. Heart and great blood-vessels normal.

Abdominal Organs.—The scar in the right hypogastrium extends straight down through the muscles and peritoneum, presenting in its whole course a dark discoloration. The internal mark of it lies right over the head of the cæcum, but nor this, nor the underlying very long appendix, nor any of the intestines or structures in the neighborhood show the slightest signs of injury, nor could the bullet be found after the most careful examination. Stomach, liver, and pancreas normal; spleen large, dark (weight fifteen ounces); kidneys both congested, right larger; intestines normal; bladder very full; testicles in a state of subacute inflammation.

On resuming, we find the following points of interest in this case: 1, Temporary paralysis of the facial muscles; 2, prolonged subnormal respiration, pulse, and even temperature; 3, no interference with assimilation and sleep; 4, absence of paresis, normal pupils; 5, some mental excitement, followed by mental clearing, and ending on the day of death, with unusual brightness and ease; 6, after four months the appearance of convulsions bearing epileptic character; their probable disappearing after the operation; 7, considerable loss of hearing on the wounded side, but no disturbance whatever of any other of the special senses.

To the end, let it be added, that the patient's mental condition was always much nearer simple hypochondria than insanity, and also, that his intelligence was rather above the average, so that no symptoms could have been lost through one or the other of these reasons.

A SUBSTITUTE FOR THE TRACHEA TUBE.

By W. N. MACARTNEY, M.D.,

FORT COVINGTON, N. Y.

On several occasions during the past few years I have used, in the operation of tracheotomy, a little appliance—I can hardly dignify it by the name of instrument—as a substitute for a trachea tube, and it has invariably given me such perfect satisfaction that it has seemed to me proper to give a description of it in the hope that it may render others an equal service.

The appliance is simply a wish-bone-shaped piece of wire, intended to keep the edges of the tracheal wound sufficiently retracted to permit easy respiration and to be self-retaining.

It has some essentially practical advantages in certain cases over the trachea tube: in its adaptability, for it can be made to answer the purpose nicely in almost any conceivable case of tracheotomy or laryngotomy; in its availability, for it can be made at almost any time and at any place at a moment's notice; in its economy, for it costs absolutely nothing, which is certainly more than can be said of the trachea tube.

Of late years the use of O'Dwyer's tubes has materially diminished the number of cases in which tracheotomy is necessary, but there yet remains a large class of cases of laryngeal stenosis from various causes, for which intubation is either not adapted, or for other reasons cannot be performed, so that the operation of tracheotomy is destined to hold a legitimate and useful place.

For instance, the country practitioner finds himself miles from home, perhaps leagues from a brother practitioner, and confronted with a severe case of laryngeal obstruction. It may easily happen that, not knowing the nature of the case when called, he finds himself without the proper appliances for its relief. The case is urgent, perhaps very urgent. He must operate at once or let the patient die. There is no time to send to the city for a surgeon, who might possibly arrive in time for the funeral sermon, or for that matter, to send home for a trachea tube.

Again, take the practising physician in the city. He also has an urgent case. His patient is cyanosed, or perhaps when he has reached the bedside respiration has just ceased. Will he delay to call in capable assistants, to procure a set of O'Dwyer's tubes, to secure a tracheal cannula of proper size and correct curve, to have everything on hand which may possibly be required, and to take every precaution in regard to antisepsis, or will he operate at once?

It is true that these are emergency cases, but they are not overdrawn. I have had to operate more than once under similar circumstances, and it has been my fortune to see others operate at a moment's notice. I have seen Dr. Stuart Douglas, then resident physician to the insane at Bellevue, open the trachea at midnight with a penknife. He did not practise surgery ordinarily. I have no doubt he would have preferred daylight and a scalpel, but there was not a moment to lose and he had the courage of his convictions.

I recall a similar instance happening shortly after where the operation was done in much the same way. There was no lack of instruments in a neighboring ward, but there was not a second to waste. Then again I saw a man suffering from a severe case of Ludwig's angina or submaxillary cellulitis. The swelling was immense, increased rapidly, the cellular tissue in the

floor of the mouth was gangrenous. He could not swallow, could not open his mouth, and respiration was extremely difficult. He finally became cyanosed, and immediate preparations were made for a tracheotomy by the attending surgeon, Dr. S. J. White, now of Franklin, N. Y. Before, however, the preparations were complete the man suddenly ceased to breathe, became pulseless, and to all appearances was dead. Dr. White seized a scalpel and with two rapid but sure strokes of the knife had the trachea open. Five minutes later, respiration having been established by the usual means, he was sitting up in bed with a good pulse and breathing easily.

Another case in point: I was hurriedly called to a case of deep-seated abscess of the throat. The patient was breathing with great difficulty. Ether was given, I evacuated the abscess, which contained about half a pint of pus, but respiration became rapidly worse, and before I had laid the knife aside he ceased to breathe and became pulseless. Artificial respiration and other measures failed. A hurried examination showed œdema of the glottis. I could have procured an intubation set or a trachea tube in three minutes. But I could open the trachea and save two minutes and three-quarters, and I did. The patient never found any fault with me for doing it hurriedly, though he has had some years of good health in which to think it over.

These are merely illustrative cases. Instances of this kind have occurred and may occur at any time to any of us. I could cite others from my own personal knowledge, but it is unnecessary.

It is an axiom that every practising physician, no matter what branch or specialty he may follow, should be able to open a trachea properly and rapidly in an emergency. He may be called upon to do it on short notice, in the absence of skilled assistants, and without all the instruments which he might desire. Perhaps he has not an intubation set; he may not have even a trachea tube, and it may even be that none of his brother practitioners within easy reach has one. Probably he has a tube or two, but not one of the proper size or shape for the particular case in hand. In such a case will he wait for the mails to bring him one from the instrument-maker?

If tracheotomy is necessary, and a trachea tube of the proper curve, calibre, and construction is not at hand, what must he do? Theoretically he should open the trachea at once. But to use a quotation now worn threadbare, "It is a condition, not a theory, which confronts us." Does the average rank-and-file practitioner not specially skilled in surgery do this? I am not aware that there are any statistics bearing on this particular point. It is to the credit of the profession that so many physicians do operate under the most adverse circumstances. But others find excuses. I know of one case at least in point. The doctor had no instruments with him for the case. He was not sure of his operative skill. He was not sure that the patient would live if he operated. He was reasonably—very reasonably—sure that she would die if he did not operate. So he informed the friends only of that which he was "reasonably" sure of. Good logic, but poor practice.

It seems to me therefore that any suggestion which will facilitate the performance of tracheotomy may not be wholly without value. The operation in itself is not difficult under ordinary circumstances. For the deliberate operation the trachea tube is well suited; but for the emergency cases this little wire substitute serves an excellent purpose, in that an instrument always at hand is worth at least two in the shop. It can be made in a moment and a tube can be sent for if needed at the doctor's leisure.

Another case of a different type: A man, while engaged in his trade as blacksmith, was kicked by a horse, the toe cork striking his larynx. When I first saw him he was enormously swollen with emphysema from the lower edge of the sternum to the crown of his head. His neck was nearly as large as his body, and the inside of his mouth and throat was emphysematous. He was deeply cyanosed and breathing with extreme difficulty. A diagnosis of fracture of the larynx was made and his windpipe was opened with some difficulty owing to the extravasated blood and the enormous depth of tissue which covered the trachea. No tube could be found to reach the tracheal cut, although several sizes were tried; a substitute was used and later an extra long tube was made purposely at an instrument store. He had an attack of pneumonia, but recovered, and the tube was removed after some weeks.

These are the cases where our most skilful and well-equipped surgeons find themselves at a disadvantage occasionally. I have in my office several extra long tubes which were made for such cases as the above, and for cases of inoperable tumors of the neck. In one case of the latter kind we could not find in New York City a tube long enough to reach and used a large silver catheter for the time, which proved a serviceable but extremely awkward arrangement. Then there are cases of submaxillary cellulitis, where the jaw is temporarily but firmly closed, and therefore an intubation tube cannot be used. The swelling in the tissues of the neck is often so great that an ordinary trachea tube will not reach. These are cases also where this little substitute is applicable and in which it fulfils an excellent purpose.

Laryngotomy also calls for a special tube flattened from above downward. With this little retractor in the larynx one can wait for a suitable tube by mail, or by freight for that matter.

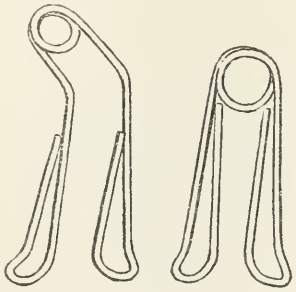
The first time I used this modest little substitute was in a case of foreign body in the windpipe. It had been in for some weeks, and the consulting surgeons opened the trachea and made a thorough but unsuccessful search for it. This failing, nothing remained but to trust to its natural expulsion. Several trachea tubes were tried, but it was very evident that the foreign body was much too large to escape through any of them. To meet the necessities of the case it occurred to me that a wire retractor could be constructed, and this little affair was the result. It opened the trachea widely and answered the purpose so satisfactorily that I have used it since then.

A very good method of handling these cases—the so-called operation without tubes—is to introduce a suture into each side of the trachea and fasten with an elastic band behind the neck. Yet there are some cases where this procedure will not work well; and it is, simple as it seems, frequently very difficult of performance, particularly in those very cases of emergency for which it seems so well adapted and for which this same procedure is recommended. It appears easy, and yet, with a poor light, with great swelling of the tissues in front of the trachea, with a thick-necked patient, in the cases of children, with a shuttle-like trachea moving rapidly up and down, and in the absence of a properly curved needle and a suitable needle-holder, I have found it wholly out of the question.

The retractor which I have used has always answered every purpose. It reduces the number of necessary and essential instruments to one—a knife. It does away with all excuses. It is practically always on hand, in any place, at any time. If a tracheotomy must be done at a moment's notice, the handle of a scalpel, a pair of forceps, a hair-pin, will keep the trachea open long enough for one to be constructed.

Stove-pipe wire will do, or better, the stiffer tinned wire from the stub of an old broom, or from the stylet of an English catheter. If your patient has neither stove nor broom in the house, and there are none in the neighborhood, it will be a pretty poor country to live in any way. But in this emergency a probe from your pocket-case or a hair-pin may be bent up properly—any straight piece of wire, or even a crooked piece—which will give

him a chance to see a change of administration. Bend the wire up in the shape of a wish-bone. Give a turn in the centre or joint of the wish-bone around a lead-pencil



or a thermometer-case, to give it the necessary spring. If stove-pipe or other soft wire is used give it two or three turns. Bring the sides parallel. Bend up the ends of the wire so as to form broad fenestrated blades or loops. Give these blades a slight outward bend at the ends to make it self-retaining. You can do all this with your fingers if you have no pliers or artery clamps handy. Close the blades and insert into the tracheal slit. Release the blades and it retracts the edges of the tracheal wound and retains itself. You can make one of nickelled wire the next day if you choose. In the meantime you can go to bed.

To summarize and recapitulate, this simple tracheal retractor is the best device with which I am acquainted in cases of tracheotomy for foreign bodies in the trachea or bronchi, where a trachea tube is worse than useless. The retractor acting as a speculum gives a free and unobstructed view of the interior of the trachea, dilating the opening to its fullest extent, and unlike the trachea tube, which furnishes an obstacle to the escape of the foreign body, it affords every facility for its expulsion during one of the coughing spells.

It can be adapted to any case of tracheotomy or of laryngotomy by making the blades long or short, curved or straight. Extra expansile strength where the trachea is rigid and resistant can be secured by making the coil at the centre smaller, by doubling the wire, or by using heavier wire.

It is useful as a retractor before the trachea is open, when in the absence of help one is compelled to do the operation unaided, in retracting the skin while the trachea is being steadied for the incision.

It has never caused irritation or discomfort, and patients on whom it is used do not complain of it. I have often seen ulceration of the trachea caused by the trachea tube. I have never seen it occur with this. In fact I do not see how it can occur to any extent if the retractor is properly made.

It has no tendency to slip out or in. It can only get partially displaced by swinging round at right angles to its proper position, when the blades would then lie in the angles of the wound. This is immaterial, inasmuch as it will even then keep the trachea as well open as before.

It will not clog with mucus in the absence of the doctor, and thus endanger the patient's life as tubular arrangements are prone to do.

It is eminently the appliance in emergency cases, being always available, and, lastly, it costs absolutely nothing.

One objection to its use might be in certain cases the presence of severe hemorrhage when the trachea is opened. In practice I have never found it so. By inserting the retractor and turning the patient on the side, or sitting him up leaning slightly forward, the blood will not run into the trachea, and any bleeding vessels can be readily caught and ligated if need be with the retractor *in situ*.

ROUTINE MEDICATION IN ASYLUM PRACTICE.

By W. A. McCLAIN, M.D.,

ATHENS, O.

A STRENUOUS effort is being made in many States of the Union to divorce the public institutions of charity from the control of political organizations, and place them under the control of non-partisan boards of supervision. This is certainly a praiseworthy effort and will meet the hearty approval of all right-minded citizens, especially among those in the profession of medicine. I desire more particularly to point out the pernicious results of political preferment in connection with the various hospitals for the insane throughout the country. For it is in the peculiar, I might say special, work of these institutions that incompetency may not only result in loss to the patient of the necessary intelligent treatment they demand, but it may entail upon them needless suffering by the unscientific application of means at hand, and a baneful routine system of medication by unskilled physicians.

The fact is patent and undeniable that of all classes of patients none call for a more intelligent and scientific acquaintance on the part of the physician with the principles of medicine and their application to the morbid conditions of mankind, than do the unfortunate insane. That they do not always receive this, may be easily ascertained by an investigation of the methods pursued in most any of the institutions of the land.

In the *American Journal of Insanity* for October, 1894, appeared a criticism on Dr. Weir Mitchell's address to the Medico-Psychological Association, by Dr. Channing, in which he disagrees with Dr. Mitchell in the latter's Utopian views of what an institution for the insane should be, and how conducted. While we admit that the criticism in the main is just, yet Dr. Mitchell certainly struck the right chord in directing attention to the fact that a much-needed reform in asylum work is a crying need. Where this fault lies, and upon whom the blame rests for such faults, I shall endeavor to point out in this paper.

Having visited the hospitals for the insane in many States of the Union, and having studied the reports from the majority in both the United States and Europe, I am more than ever convinced that a vast amount of routine treatment, so far as medication goes, is the rule, and the absence of it the exception in these institutions; while all alienists will admit that the greatest benefit derived from these institutions is not from any course of medication, but from gentle restraint, pleasant surroundings, change of environment, which the patients enjoy, and the regular life to which they are subjected.

From these sources we look for the greatest good. While these conditions in the vast majority of cases produce marvellous results, yet they cannot take the place of careful medication in many singular morbid conditions to be met with among the insane. To illustrate, let us take the ward physicians in most any of our hospitals for the insane. They are mostly young men who have had little or no experience in general practice. They have treated some of the more familiar diseases, some of the epidemic diseases of childhood, have read some text-book on practice, and have a very hazy idea of the subject after all. If a patient is able to describe to him all his aches and pains, and lay before him a complete history of his case, then, according to rule 1, 2, or 3, he may pronounce the case one of asthma, whether caused from reflex nervous trouble or heart disease, he is not quite certain which. The various valvular lesions of the heart he has never had any clinical experience to enable him to distinguish, and the curious murmurs and turbulent sounds convey to his intelligence nothing of diagnostic value.

And perchance it may be lung trouble; here again

the average ward physician is all at sea. The sounds he hears may be all right or all wrong, but he could not be qualified to determine. In fact, if one-half the physicians who place their ear to the chest in such a knowing way were asked by a scientific clinician to state what they heard, expected to hear, and what it all signified, they would stand speechless with doubt and ashamed of their own pretences to knowledge.

Again, when we come into the domain of the diseases peculiar to women, how very far from the truth are their professions and practices. In no class of practice are these diseases so wantonly neglected as in asylum work, and no class of cases demands so careful and painstaking knowledge as do the manifold diseases of women. Owing to the complicated and extensive nervous mechanism of the organs of reproduction in women, any disturbance in this region must necessarily affect the general nervous system very profoundly, and calls for a critical examination to discover the cause that its removal may be possible.

But what do we find when we look in this direction? While nearly all the State hospitals for the insane are thoroughly equipped with all the instruments needed for careful examination and operation, yet the uterine sound, the speculum, and the curette are seldom or never used. Why this dereliction of duty? The reason is plain again. What have these young and inexperienced physicians learned of the diseases of the uterus and its appendages? Their knowledge is usually so indefinite in regard to these conditions, that anything they may do would be done blindly and misguidedly. They remember having seen at the free clinics, when they went to college, some application made to the uterus by means of a pledget of cotton, saturated in some astringent solution. They go through the same manœuvre, but just what results they expect from this treatment they are not able to state. And yet I have known poor deluded patients who submitted to this for months, under the impression they were being treated for womb disease. No amount of glycerine and tannin applied to the neck of the womb would ever, in the least degree, arrest or mitigate a diseased process of the tubes. And yet this is the routine work.

I recall one instance in a certain asylum, in a Western State, where a patient was permitted to go home to die from some unknown disease, and yet there was every evidence of an enlarged uterus many times its normal size. An examination in this case had never been made. Another case was entered on the books as "acute melancholia," due to domestic trouble and worry. The patient had not menstruated for six months, and yet there were no indications of pregnancy. She was sent back to the ward, and the usual routine medicines were administered to produce sleep. The patient did not improve, and her family took her home, where she fell into the hands of a specialist in diseases of women. He dilated the neck of the uterus and curetted its cavity, and placed the patient on permanganate of potash and laxatives. The menstrual function was re-established and her mind improved from that moment. To trace the exact cause and connecting links in this case were difficult indeed, but it is evident it was not organic brain disease alone. These patients cannot, as a rule, tell their troubles and ailments in an intelligent manner. Nor will they usually answer any questions put to them by the physician, and in such cases the medical attendant's duty is plain and should not be shrunk from—a careful and thorough examination of every organ of the body so far as practicable. The insane are subject to all the other diseases one meets with in general practice, and it is seldom, indeed, that we meet with a mental disorder independently of other and organic trouble, if we could only know how and where to look for the lesion. One other instance occurs to my mind: A young man was arrested for attempted homicide. While in jail he showed marked symptoms of insanity. A physician was called, the patient was probated and sent to an asylum. His case was entered on the books as "acute mania." He was put in the back ward. Of course the young man was insane, but why? This was not asked, but large doses of duboisine and morphia were given to produce sleep and quiet. No careful examination was made; the case grew worse, and in about ten days the patient suddenly died. On post-mortem it was found the cause of death was due to an abscess in the mastoid region, and the insanity to the meningeal inflammation. An early recognition of this condition, and a minor operation in surgery, would in all probability have saved the individual's life. These are but a few of the many cases of routine medication which prevails in most of our hospitals for the insane.

It is so easy to fall into the habit of thinking that all insane persons are suffering from some mysterious affection of that still more mysterious and intangible something called mind, and inasmuch as they know but little of the nature of mind, and the normal processes of thought and feeling, how can it be possible for them to conceive of any method of treating that which they do not understand and thus fail to recognize?

Mental disease cannot exist in a perfectly sound physical organization. That this is at variance with the views expressed by some authors on metaphysics, I am well aware, but to assume otherwise is certainly contrary to all we know of the pathology of mind, and the advanced writers on mental science no longer speak of the relation of mind and brain as the "player and the instrument." Simply because we fail to discover the pathological condition of nerve cells in these cases is no evidence that it does not exist. Our knowledge of the minute anatomy of the brain and its complex physiology is at present very imperfect. Moreover, the pathological condition which underlies insanity—the deep substrata—may exist in any other organ of the body aside from the brain.

If we but apprehend clearly that the relation between the supreme nervous centres and the blood is but the same as exists between the blood and other parts of the body, and that the disordered mental phenomena are but the functional exponent of morbid organic action—when we grasp this just conclusion, then we will look for physical causes and seek to destroy the tree of insanity by killing its roots and not by lopping its branches. A delusion, in the minds of most physicians, is some terrible octopus which settles over the brain like a canopy and obstructs all the avenues for the exit of healthy, rational thought, when, in fact, a delusion is nothing more than the belief in an hallucination, which, in turn, is but sensations of subjective origin interpreted objectively, just as persons who are victims of vertigo are suffering from motor hallucinations.

Mind and matter are not two separate entities, neither are they to be thought of and studied as such. Mind is no more apart from brain than sound is from the organ of hearing, and any philosophy which would teach that the mind is anything other than a function of the brain is fallacious, and leads only to mysticism.

One other organ, the diseased action of which may cause a morbid condition of mental processes, must not be overlooked, and that is the stomach or digestive tract. Even in epilepsy it has been observed that laxative medicines, like calomel, when administered, will defer the threatened epileptic seizure, by clearing out the alimentary canal and by increasing the secretion of the various digestive juices, and by some unknown alterative effect upon the nervous centres. The stomach's relation to the system of the great sympathetic is marvellous.

No single organ of the body exerts a more decided influence upon the mind than the stomach. The myriad symptoms of uneasiness and nervous perturbations, the morbid appetite, the impulsive nature and irascible temper, are a few of the symptoms due to dis-

ordered digestion, especially that caused by chronic malarial poisoning, and not infrequently these conditions result in a form of mild melancholia, or at least are the exciting causes.

That dream-life is closely associated with the condition in some forms of insanity is recognized by all psychologists, and what uncanny dreams and inexplicable nightmares possess those who suffer from indigestion! If this be true of dream-life, why may it not be true of waking existence? For it is only a matter of degree in the diseased condition, yet in the wards of most hospitals for the insane are many patients who receive no medication whatever, and who are suffering from stomach or intestinal indigestion—and there is no diseased condition which places an individual in the hands of the demon of unrest as does intestinal indigestion. If a patient should call on the ward for medicine and speak of some pain or uneasiness, the ward physician, in the majority of instances, would set it down as a delusion or whimsical demand, and it goes unheeded. I am fully conscious of the many difficulties to be encountered in an attempt to fully understand the exact mental condition of any person. Insanity is not a condition to be diagnosed by the aid of the stethoscope or thermometer, but its diagnosis rests upon the skilled judgment of those who have made the phenomena of mind a careful study, and in addition to this have studied the insane and are familiar with all the hidden springs of their actions, and have traced every impulse to the secret founts of their being. Such are able to interpret much which to the unskilled would be only meaningless and purposeless acts, or the silly mutterings of delirium.

I am aware that many who read this article will not admit the justice of the criticism, but all who have had extensive facilities for studying the subject and of verifying the truth of the statements must have already noticed the same.

Now, if these conditions exist, where rests the blame, and how may it be remedied? First let me say that all this is no fault of the superintendent, and inefficient ward physicians is no wish of his. The arduous and exacting duties of his position render it impossible for him to give any special study to each individual case. A superintendent's qualifications should be more of an executive nature than of a skilled pathologist; the medication must rest with the ward physicians.

And so long as these institutions are subject to political caprice of the dominant party, just so long will the ward physician be selected from a class of physicians who by nature and education are unfitted for the position, and who from the very nature of their requirements must fall into a routine system of medication. And so prone is the human mind to be satisfied with its own work that it soon becomes blinded to those higher lifts of sky and broader reaches of horizon in the realms of research which lie out and beyond. And as the "fire-fly only shines while on the wing, so with the mind when at rest—it darkens."

Walking Backward Cure for Headache.—An apostle of physical culture says that an excellent and never-failing cure for nervous headache is the simple act of walking backward. Ten minutes is as long as is usually necessary to promenade. It sometimes, however, requires more than ten minutes to walk at all, if one is very "nervous." But it is not understood that it is necessary to walk a chalkline. Any kind of walking will do, provided it is backward. It is well to get in a long, narrow room, where the windows are high, and walk very slowly, placing first the ball of the foot on the floor, and then the heel. Besides curing the headache, this exercise promotes a graceful carriage. A half hour's walk backward every day will do wonders toward producing a graceful gait.

SOME OF THE DISADVANTAGES OF SPECIALISM.

By WOODS HUTCHINSON, A.M., M.D.,

DES MOINES, IOWA.

THE microscope is a wonderful instrument, but it has its limitations. Inability to see anything half an inch beyond its own objective, for instance. It will detect a bacillus anthracis, but fail to see a panther or a trolley-car. And the knowledge of the specialist is liable to similar defects. The more completely he concentrates his attention upon one thing the blinder he becomes to all surrounding objects.

Probably there is nothing of which we, as a profession, are prouder than the remarkable division "of labor" which has taken place among us. It is a mark and a means of progress, and plays the same *rôle* as in other departments of civilization. The specialist has arrived and we bow down before him, for through him alone comes accurate and scientific knowledge (and superb fees). Nay, more, we are, most of us, one of him ourselves, or trying to be, for the pure and intellectual joy of possessing the knowledge aforesaid, of course. The advantages of specialization and the advances due to it are, of course, unquestionable and glorious, but are we not in danger of overdoing it? As to the injuriousness of one of its prevailing tendencies there can be little doubt, and that is the alarming fact that few or none of our present medical students are qualifying themselves (in intuition) for general practitioners; they are all going to be "specialists;" some for the glory of the thing, others for the pay, and others because "there are no night-calls to make." All of which is about as rational as if a "kindergartner" should announce his intention to confine his attention to the Italian verb as soon as he had learned to write. It ought to be actively discouraged by both medical teachers and the profession, and at least two to five years of general practice insisted upon as a proper part of the preparation for any special work.

A specialty should be drifted into by a sort of natural selection, after a man has tried his strength and ascertained his tastes by years of general practice. No man can hope to properly understand any single region or organ of the body or class of diseases who does not first thoroughly understand the whole body and its variations, both in health and disease. The bouquet-maker may get along with a knowledge of the blossom alone, but the horticulturist, the botanist, must know the whole plant-family from rootlet to seed-capsule, their needs, their habits, everything about them, in fact. But the undesirable consequences to which we specially refer are those to the specialist himself and to the profession at large. Specialization in essence is limiting, narrowing of one's interest to a single subject or group of subjects, and unfortunately this narrowing, while necessary, may be highly injurious to the general mental development of the student. So much so in some cases as to actually defeat its own ends, just as a high degree of myopia may interfere with a man's reading even German brevier at six inches. The specialist is in peculiar danger of seeing the whole world through his own particular spectacles. To the gynecologist woman becomes simply a uterus and its appendages, and every disturbance of her nutrition must originate in these organs. The rhinologist traces everything from asthma to insanity to hypertrophy of the turbinated bodies, while the proctologist is sure that the true view of most diseases can only be obtained through a rectal speculum. To such an extent does this biassing of view extend as to actually blind him in many cases to the fact that some diseases he is called upon to treat may be merely extensions of general pathological changes of the whole system into his particular preserve. For instance, we recently heard of a case of rapidly developing double cataract in a young adult

who had consulted two ophthalmologists, and been advised by both to have them extracted. A general examination revealed sugar in the urine and well-marked symptoms, both local and general, of diabetes. Some of the most distressing mistakes we have ever seen in practice have been made, not by obscure country doctors, but by specialists of skill and wide reputation, whose ciliary mechanism had become permanently "accommodated" to the range of their particular hobby only.

Perhaps for the advance of medicine as a science, the more minute the specialization the better, but for its practice as an art, almost the reverse is true. No organ has as yet succeeded in existing by itself alone, and the average human being will insist upon having a full set of all the mechanisms belonging to the species, so that complications are liable to occur at any moment. And we must be prepared for any and all of them. As the human frame is at present constructed no man can hope to practise any specialty with comfort (to his patient, at least) and credit, without a fairly thorough working-knowledge of the structure and diseases of all its parts. In short, the man who knows only his specialty, does not know even that as he ought to. He suffers from mental myopia, so to speak. Another undesirable effect of specialization is the temptation it affords to multiply refinements, distinctions, and divisions with corresponding technical terms at portentous length and appalling sound. So far has this been carried of late, that the papers read in many of the sections of our medical gatherings are wellnigh unintelligible to the average general practitioner from the technicality of their language, and their subject-matter so absolutely divested of all relation to or bearing upon anything else under heaven, as to be utterly uninteresting and valueless to all but a chosen few. More than this, the very fact that our chosen field is small renders us even more liable than usual to that common human delusion, that we know all there is in it. We are sometimes even proud of our ignorance of other departments of the healing art. And this is unfortunate, for diseases are most inconsiderate, and often absolutely decline to limit their action to any given region or organ. Two or three of them will even mix themselves up in the same subject. For instance, if an ophthalmologist were called to treat the primary conjunctivitis of measles, he would be under the painful necessity of calling in a laryngologist to attend to the naso-pharyngeal complications, a chest specialist for the cough, and a dermatologist for the eruption, which would be somewhat fatiguing for the patient—as well as expensive.

If the present rate of progress continues, the neurologist in charge of a case of locomotor ataxia will have to call in a genito-urinary specialist when cystitis develops. It has gone almost to that extent already, for as Hughlings Jackson not long ago remarked at a medical gathering where it had been stated that every organ in the body had hospitals specially devoted to its treatment except the umbilicus, "You forget, gentlemen, there is, in this very city, a *naval* hospital." And any physician who can treat only a fraction of the body is very apt to become only a fraction of a doctor himself. Far more valuable than mere knowledge of facts to the consultant is judgment, ability to balance probabilities, and this can never be developed by the hemocytometer or the cystoscope alone. Indeed, the more canvas of mere special information that an expert carries in proportion to his beam of broad culture and his ballast of common-sense, the more unsteady his course is likely to be. Not only a thorough knowledge of all human medicine, but a fair acquaintance with some of the allied natural sciences, is really requisite for the soundest judgment and the clearest insight, and this not merely for his own, but also for his patients' sake. Such a man will make fewer mistakes and be more likely to assist nature, instead of hindering her, than many a mere technical expert, even in the latter's own domain.

One of the most strikingly unfavorable results at specialism is the extraordinary impetus which it has given to our natural tendency to run after professional fads. The air has fairly echoed for the past fifteen years with superb trumpetings of wonderful discoveries from one expert quarter after another, followed by a wild stampede of the profession in that direction. Now a shout goes up that the chief cause of neurasthenia and hysteria is an elongated cervix uteri, and the cure is to split it; five years later another authority has the floor and is equally certain that all these things are due to a lacerated cervix, and all that have been split have to be repaired again. Again, the ophthalmologist gains the professional ear, and all forms of backward cerebral development short of idiocy are to be relieved by correcting the refraction, and a host of nervous disturbances, from neurasthenia to epilepsy, are to be cured by graduated tenotomies of the recti muscles.

Next, the bacteriologist takes the rostrum, and, according to him, nearly every form of diseased action, from coryza to hydrophobia, is due to the pernicious activity of some germ. The only thing that is needed is to identify your germ, administer an appropriate germicide, and the thing is done. The cells of the body are mere clay in the hands of the potter before the dread bacterium. The only thing that has prevented this particular craze from absolutely revolutionizing therapeutics has been the impossibility of finding any antiseptic that would not kill the patient long before it could the germ. This, of course, matters little in Germany, but it is a serious drawback here.

Next, the cerebral surgeon gets in the saddle and announces his intention of preventing idiocy in the future by cutting slices out of the thick skull, which alone prevents the brain from growing. If this line of argument be followed out we should all be more intellectual without any skulls at all, simply protecting our surging brains by a steel-ribbed hat of some sort, through which we could talk to our hearts' content—just like these craniotomists did.

Last, and worst of all, is the gynecological brass band which is in full blast at present, whose Wagnerian *Leit Motif* is that the most dangerous and deadly thing which a woman can have concealed about her person is an ovary. I say worst because its echoes penetrate everywhere, and the county-seat doctor with any pretensions to surgery who has not done a dozen celiotomies is positively ashamed of himself.

However, a healthy reaction against such crazes is setting in at last. The specialist is beginning to acknowledge his dependence upon the practising physician. The oculist is finding out that many of his cases of asthenopia need iron and sunlight rather than lenses. The rhinologist finds that he obtains more permanent results in "catarrh" by attending to the skin, the circulation, and the muscles of his patient. The bacteriologist has already come to see that the fluids of the bodies of certain animals contain sozins and alexines which are even more deadly to bacteria than mercuric chloride, and may even admit the same to be true of human nuclei before long. As for the gynecologist, his own excesses are proving his ruin, for he is rapidly approaching the point where he will have to be tolerated as a nuisance. Even the inaccessible and haughty neurologist is compelled to admit that several of his choicest and most elaborate diseases are due to ordinary intestinal ptomaine-absorption or common every-day syphilis. The humble general practitioner is the real "Iron sides" of the army of medical science.

Medical Ethics.—The *Columbus Medical Journal* states that out West it is not considered ethical for a doctor to have an office in two different villages.

Progress of Medical Science.

The Hygiene of the Kidney.—Dr. J. Henry C. Simes calls attention to the relation between the skin and the kidneys, and observes if the skin is not in healthy condition the kidneys have an extra volume of work to perform. The importance of a healthy action of the kidneys is manifested by the fact that serious trouble may arise in other organs, as heart, lungs, brain, and nervous system, when the excretory work of the kidneys is imperfectly done. In watching the action of these organs many factors must be taken into consideration, such as the nature of the diet, the amount of liquids consumed, the nature of the exercise and activity of perspiration. Then again, as the urine varies so much, a correct examination cannot be made unless the entire amount voided in twenty-four hours be collected, and a specimen taken from this. The quantity of urine varies greatly with the amount of liquids holding the solid constituents of the food in solution. When it is remembered that nine hundred and fifty parts of every thousand of the urine are water, the importance of this element in the dietary becomes evident. On this point, the author is strongly of the opinion that the majority of men eat too well and do not drink enough water. As a result of this, there is deposited in the tissues many effete products that should be carried off by the kidneys. The work done by those organs is in this way interfered with ; and in time organic disease often comes on. It is owing to the large amount of water that much of the benefit from a milk diet arises. In advocating the use of abundance of water with the solids, the author again calls attention to the danger of washing down the food with it, and taking time to masticate properly. While water is of prime importance, it cannot take the place of the saliva. The benefit derived from a sojourn at a mineral spring is almost entirely due to the flushing out the system gets. Waste products are dissolved and washed away by the kidneys. The opinion is expressed that pure water drank for a lengthy period would have as good an effect. This of course applies to cases where there is no organic lesion, and efforts are directed against the ill effects of a sedentary life and over-eating. In advocating the use of water, its excessive use must be guarded against. The habit of taking too much water may be indulged in. This is the other extreme, and may result in harm. The effect of water is to make the kidneys act, and by over-drinking, these organs may be overworked. The abuse, therefore, of water may prove the reverse of "in aqua sanitas." In the cold season, warm clothing is of much value, as tending to prevent congestion of the kidneys. Should such happen, it must be relieved by acting upon the skin and bowels. Judicious bathing is useful, as tending to maintain the healthy action of the skin, and thereby avoid congestion of the kidneys. If many people drank more water, and used less solid food, kidney diseases would not be so common as they are at present.—*Dietetic Gazette.*

A New Method of Abdominal Hysterectomy.—According to the Paris correspondent of *The Lancet*, M. Richelot has devised an original and improved method of performing this operation. He claims for his procedure great advantages over the current methods, which are long and laborious, and the quicker methods sometimes employed, which are frequently attended with danger. The principal advantage of M. Richelot's manner of operating lies in the complete absence of ligatures and sutures, forci-pressure only being used. A scalpel, a dissecting forceps, a long and a short hæmostatic forceps, and finally two long Richelot's forceps provided with a long "bite"—this is the only armamentarium necessary. The patient is placed on her back and the operator takes his station between the separated limbs. The vagina is first thoroughly disinfected, for in the course of the operation the surgeon's hand passes alternately into that canal and the abdomen. The usual abdominal incision being made, the uterus is enucleated and laid on the abdomen, covering the lower angle of the operation wound. [When fibromata occupy the lower segment of the organ the usual fragmentation is at once practised ; when, however, they are interstitial they are left untouched, and the operation is proceeded with as follows.] An anterior peritoneal flap is fashioned by means of an incision across the anterior surface of the uterus, extending from one broad ligament to the other. The broad ligaments are thus liberated and thrown downward over the bladder. The left index-finger is introduced into the vagina, and the anterior cul-de-sac is incised with a large pair of scissors, the discission of the vagina being pushed nearly as far as the sides of the os. Then leaving the uterus *in situ*, the broad ligament on one side is seized by the hand quite close to the uterus, an opening in the posterior cul-de-sac is made with the point of the scissors, and through this orifice is passed, *per vaginam*, the posterior limb of Richelot's forceps, the anterior limb being thrust through the corresponding hole in the anterior cul-de-sac. The forceps is then thrust from the vagina from below upward and, guided by the hand holding the broad ligament, is placed on that ligament. The same manœuvre is practised the other side by means of the second pair of Richelot's forceps. Both ligaments being seized by the forceps, they are liberated from their extreme attachments. The uterus now hangs only to the posterior cul-de-sac, which is in its turn divided with a few snips of the scissors. But as this section gives rise to hemorrhage, three hæmostatic forceps are here placed. A plug of iodoform gauze is inserted into the upper part of the vagina, none being placed in the abdomen. The abdominal incision is sutured and the operation is over. Of five hysterectomies thus practised by M. Richelot, four being for fibromata and one for cancer, the four first mentioned were successful. The duration of the operation varies from thirty to thirty-five minutes, and no complications need be feared during the healing process. M. Richelot gives to his method of operating the somewhat cumbrous name, "hysterectomie par pinces vaginales d'emblée sans ligature ni sutures."

The Etiology of Locomotor Ataxy.—Dr. Pitres, of Bordeaux, has made extensive investigations in the hope of throwing light upon the still doubtful points in the etiology of this disease. His first results were published in a thesis by Dr. Bereni and comprised 225 cases. The influence of syphilis was found to be great, but not overwhelming, and was by no means in keeping with recent ideas on the subject (*The Lancet*). In considering those cases in which the etiology was certain, there were 125 out of 225—*i.e.*, 55.5 per cent.—and even in many of these cases the syphilis was associated with other cases of tabes dorsalis as hereditary joint affections, alcoholism, sexual excess, etc., so that the exact percentage which could safely be attributed to syphilis was reduced to 22.33 per cent. Of the other patients about 33.44 per cent. had no sign of previous syphilis, and twice during his experience Dr. Pitres has seen tabetic symptoms precede syphilitic manifestations, so that these statistics tend to show that though syphilis is a cause it is not by any means the only one, but that many other conditions also play their part in setting up the disease. There is also in Dr. Bereni's work a chapter on the investigation of the heredity of tabes, but no direct tendency to inheritance was found.

Anthelmintic against Tapeworm.—For this purpose, an ounce and a half of ether may be administered at once, followed in two hours by a full dose of castor-oil. —Bourdier and Hortet.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR

PUBLISHERS

WM. WOOD & CO., 43, 45, & 47 East Tenth Street.

New York, October 12, 1895.

THE ADULTERATION OF DRUGS.

We are in receipt of an address delivered before the Brooklyn Institute, by Professor Willis G. Tucker, upon the adulteration of drugs. Dr. Tucker is professor of chemistry in the Albany Medical College, and director of the New York State Health Board Laboratory. His remarks upon the subject of adulteration, therefore, should carry with them much weight. We have already made some criticism of the results obtained by the State Board of Health through their investigations as to drug adulteration. Dr. Tucker's present address, however, is in some sense supplementary to the report in question.

During the years 1891–94, inclusive, 8,305 samples of drugs were examined. Of the total number, not one-half could be rated as of good quality; about fifteen per cent. were of fair quality; and about thirty per cent. were of inferior quality. Of course, many of these drugs were substances not commonly used or substances of no very great importance. There were, however, a number of useful drugs to the adulteration of which Dr. Tucker called special attention. It is his belief that many of the old-fashioned remedies have gone out of use, not because better substitutes have been found, but because they are so generally of inferior quality as sold in the stores. Thus, out of 607 samples of Hoffman's Anodyne, only 153, or a little more than one-quarter, were found to be of satisfactory quality. Ordinary Hoffman's Anodyne, as usually furnished to physicians, is simply a mixture of alcohol, ether, and water, without any of the ethereal oil on which the virtue of the original preparation was based.

Sweet spirits of nitre is another of the old-fashioned drugs which is seldom found of good quality. Chloroform was found to be impure in 26 out of 123 samples. Precipitated sulphur was found to be impure in three-quarters of the 248 samples examined. Cream of tartar (potassium bitartrate) was of fairly good quality when purchased at drug stores, but at the retail grocery stores fully one-half were found to be impure specimens. Among other articles of an inferior quality are mentioned the bromides of potassium, sodium, and ammonium, and the iodide of potassium.

There is another class of drugs which become more or less deteriorated as a result of age or exposure. Carbonate of ammonia, aqua ammonii, magnesia, and lime-water are the four drugs especially mentioned by Dr. Tucker.

Among articles which are likely to be of inferior strength or short weight are the dilute acids of the Pharmacopœia. Hydrocyanic acid is particularly mentioned. Reduced iron is found to be rarely full strength, and Seidlitz powders are frequently of inferior quality. Among drugs substituted there are mentioned saffron, ether, creosote, distilled water, sulphur, and solutions of citrate of magnesium.

THE DISINFECTION OF ROOMS AFTER INFECTIOUS DISEASES.

The absolute disinfection and sterilization of a room in which a patient with an acute infectious disease has been treated, is considered at present extremely difficult, if not impossible. We refer, of course, to rooms in ordinary houses which cannot be washed down with large amounts of strong antiseptic solutions. The usual procedure of burning quantities of sulphur, of washing the walls and removing all movable pieces of furniture, is considered to be all that is practically possible. Dr. G. Barnet has been working, in co-operation with Dr. Trillat, for the purpose of determining whether a better method cannot be found for the disinfection of infected rooms, and he claims to have obtained successful results. The substance which he used is a solution of formaldehyde in alcohol. He has devised an apparatus by which the vapors of this substance are diffused through a room, and he says that with it he can disinfect with absolute certainty in six hours three hundred cubic metres of air. Cultures of various specific micro-organisms placed in the room are rendered absolutely sterile by this process. The vapors of this formaldehyde have no injurious action upon the furniture of the room, and they disappear rapidly after a few hours of airing. The process suggested and the apparatus devised appear to us to be rather expensive, but if they do all that Dr. Barnet claims, they will prove a very useful addition to our methods of fighting disease.

THE HEART IN THE PHTHISICAL.

The necessity of a proper "soil" for the development of tuberculosis under ordinary conditions of infection is recognized by all. In what this "soil" consists, however, we do not definitely know. A "hereditary weakness of constitution" expresses about all that science has as yet determined, though to this many would add, perhaps, certain defects in the configuration of the chest and a feebleness of lymphatic and systemic circulation.

Dr. K. Oppenheimer, of Munich, has, perhaps, given one certain factor in the tubercular diathesis. He made a study of the relative weights of the organs of young people who had died of tuberculosis (*Münch. med. Wochensch.*). The number of cases studied was three hundred and five. The conclusion which he reaches is, that of all the bodily organs the heart develops less with increasing growth, and that the heart of the phthisical patient after the time or puberty is

relatively too small. Previously to that time it is relatively large. For example: In the second year of life, in the normal individual, there is 5.3 gr. of heart to 1000.9 of body; in the phthisical the relation is 3.6 to 1000. In the thirteenth year the relation is changed and becomes 5.5 to 1000 in the normal, to 5.0 to 1000 in the phthisical. This relative smallness of the heart continues until the twenty-fifth year.

The inference from these figures is, that those children who are predisposed to tuberculosis should be made to follow exercises that will cause some hypertrophy of the heart.

PENSIONS TO MEDICAL MEN.

In a recent speech by Mr. Balfour at a dinner given by the Royal Medical Benevolent College, many things in praise of medicine and medical men were uttered. Mr. Balfour kindly sets the seal of his approval upon us, for which we are duly grateful. He recognizes the great amount of time and skill which is expended by physicians gratuitously, and he has a further and practical suggestion to make in connection with it. He suggests that there should be established by the subscriptions of philanthropists, or perhaps with the help of the municipalities, funds by which the widows and orphans, and even the old age, of medical men may be provided for. We thank Mr. Balfour for his suggestion, but we do not believe that in this country it would be taken kindly. Medical men do not wish to be treated as persons who have not sufficient foresight or ability to take care of themselves. They do not belong to the indigent class, and aside from this feeling of independence which medical men, in this country at least, possess, we believe that they are as a body opposed to the socialistic tendencies which the attempt to pension the professional class would lead to. We do not know of anything which would take away the stimulus for effort more certainly than the feeling that, whatever happens, whether one be idle or industrious, evil or virtuous, there will be a provision for himself and his family.

A NEW INDEPENDENT ORDER.

There is in the *Medical Mirror* for September, 1895, a valuable historical description of the rise, development, and final effective organization of the Order of "Chutmucks," a social body connected with the workings and speakings of the Mississippi Valley Medical Association. The Chutmucks, so far as we can learn from the bibliography and history of the Order, as given in the monograph referred to, consists of persons "who know, and know that they know." The credentials or insignia of the Order are the four B's, one B standing for the Brains which direct the Chutmuck, the second for the Backbone which sustains him, the third for the Blood which pours plethorically through his vessels, and the fourth for Beauty which radiates from him. There should, we fancy, be a fifth B, which would stand for the buzzing of the wheels in the Chutmuck's head, but this is not an official portion of the insignia. At the meeting of the Mississippi Valley Medical Association, recently, the loyal braves of the Chutmuck clan presented to the President, Dr. I. N. Love, a watch, in testimony of their loyalty and affection. The purposes of the Order of the Chutmucks seem to be to encourage kindliness of heart, breadth of sympathy, optimism in judgment, healthfulness of body, and a happy combination of boastful modesty with an aggressive and inconspicuous self-depreciation. We wish the Chutmucks long life and happiness.

FORMALINE.

From the frequent references to the successful use of formaline and its preparations in the laboratory and the operating-room, it seems as if this substance were likely to take a permanent place among the useful additions to the physician's armamentarium. Formaline, formaldehyde, and formal are synonymous terms. Their chemical formation has been referred to already several times in these columns. Formaline is, we believe, the proprietary name given to a forty per cent. solution of formaldehyde, while, if we remember correctly, formal is a still weaker proprietary solution of the same substance. "It is the general opinion," says Dr. Squibb in his *Ephemeris*, "that formaline is superior to corrosive sublimate in its germicidal action and is far less toxic." Drs. Gegner and Hauser have made experiments in testing its antiseptic value, and similar work in this line has been done by Messrs. Slater and Rideal, of London. Formaline has been found to be an excellent preservative of pathological specimens, and it has largely taken the place of alcohol for many purposes in the laboratory. Formaline in two per cent. solutions is said to preserve the brain in excellent condition, as well as other tissues of the body. In the June number of the Canadian *Practitioner* Dr. Cullen, of the Johns Hopkins Hospital, describes a rapid method of staining fresh tissues by the aid of formaline. By its use a piece of tumor from the operating-room can be examined and stained within fifteen minutes. His method is said also to be very useful for the examination of uterine scrapings. The method of using formaline and its products, in the disinfection of rooms and in surgery, has been referred to before in the Medical Record, and we call attention to the subject again because it seems to us that the substance has a practical value in many directions, and that medical men should be familiar with it.

Deaths from Chloroform Anæsthesia.— Dr. J. W. Keiser, of Reading, Pa., writes to the *University Medical Magazine* that in that neighborhood a large number of the physicians are favorably disposed to the use of chloroform. Five years ago Dr. Keiser reported two deaths from the use of chloroform, occurring in his locality, and since then, he states, there have been two more.

The Rush Monument Fund.—The total of contributions to this fund amounts, to date, to $3,357.39. Recent donations to the amount of $196 are acknowledged by the committee. Further contributions are earnestly desired, and may be sent to the secretary and treasurer, Dr. George H. Rohé, Baltimore, Md.

News of the Week.

No more Infectious School Slates.—The Health Board has approved a number of recommendations suggested by Professor Herman M. Biggs, the department bacteriologist, and ordered that a copy be sent to the Board of Education. Some of the recommendations are as follows: 1. The use of slates, slate-pencils, and sponges shall be discontinued in all the public schools. 2. According to requirement pupils shall be supplied with pencils and penholders, each pupil to retain those received in a box provided for the purpose, such box to be marked with the pupil's name. Pencils and penholders shall not be transferred from one pupil to another without suitable disinfection. 3. All school property left in the school building by a child sick with any contagious disease, and all such property found in an apartment occupied by a family in which a case of small-pox, typhus fever, diphtheria, scarlet fever, or measles has occurred, shall be taken by the Health Department for disinfection or destruction. 4. Books which are taken home by pupils shall be covered regularly once each month with brown manilla paper. 5. Places for drinking-water on the ground floors of the school buildings shall be discontinued, and a covered pitcher provided for each class-room, in which fresh water shall be placed before every session. A numbered cup, to be kept in the class-room, shall be issued to each pupil. No interchange of cups shall be allowed. Provision is proposed for the exclusion of children in whose homes there may be cases of contagious disease and for a report by teachers to the Board of Health of all cases of sickness among pupils. Finally, the recommendations provide for more closet-room for hanging clothes, and prohibit principals and teachers from sending one pupil to the house of another for any reason.

An Army Medical Examining Board will be in session at Washington City, D. C., during October, 1895, for the examination of candidates for appointment to the Medical Corps of the United States Army, to fill existing vacancies. Persons desiring to present themselves for examination by the Board will make application to the Secretary of War, before October 8th, for the necessary invitation, giving the date and place of birth, the place and State of permanent residence, the fact of American citizenship, the name of the medical college from which they were graduated, and a record of service in hospital, if any, from the authorities thereof. The application should be accompanied by certificates based on personal acquaintance, from at least two reputable persons, as to his citizenship, character, and habits. The candidate must be between twenty-two and twenty-nine years of age, and a graduate from a regular medical college, as evidence of which his diploma must be submitted to the Board. Further information regarding the examinations may be obtained by addressing the Surgeon-General, United States Army, Washington, D. C.

Pasteur's Funeral.—The funeral of Pasteur took place on October 5th with great state. The President of the Republic and many civic and military authorities were present. The procession following the hearse was a mile long. The Minister of Public Instruction delivered the funeral oration.

Hydrophobia from a Cat Bite.—A boy in this city, sixteen years of age, was bitten by a cat six weeks ago. He died on October 5th, at Gouverneur Hospital. The official certificate of death states that the cause was hydrophobia. The brain and spinal cord are being examined by the pathologist of the New York Hospital.

The Illinois Medical Journal is the name of a new journal published in DeKalb, Ill., under the editorial management of Dr. H. Edward Dunlop. If it be permitted to judge from the first number, that for September, we may predict for our young contemporary a long and successful career. In the first issue, among other interesting articles, is a plea for modern Greek as an international language, by Dr. Rose, of this city. Dr. Dunlop also endorses the suggestion in an editorial note.

A New Pathological Building.—The Massachusetts General Hospital is to have a new pathological building costing about $22,000.

Diphtheria in the New York Juvenile Asylum.—The New York Juvenile Asylum has been quarantined for some time on account of an outbreak of diphtheria. In two months about fifty cases have occurred.

Prevention of Diphtheria by the Use of Antitoxin.—At a meeting of the Practitioners' Society, October 4th, Professor H. M. Biggs read a report, based on a large number of statistics, and tending to prove that by means of injections of the diphtheritic antitoxin immunity against diphtheria can be secured.

A Hair from the Dog that Bit.—The old idea that a hair from the dog that bit was good for the person who was bitten, seems to present directly the converse of the truth, as established by modern science, which is to the effect that a dose of the venom, taken under proper conditions, before the bite, will prevent the fatal consequences of the bite. Dr. G. Ranking, in the *Indian Medical Gazette*, collects a number of facts to show that in ancient times people were accustomed to secure immunity against snake-bites by taking certain substances, in which the active ingredient was the venom itself. In particular they used a celebrated Persian snake antidote, the composition of which is ascribed to one of the Persian kings. The essential ingredient, he shows was the flesh or the venom of the snake.

Inoculations against Cholera.—The results of Professor Haffkine's system of inoculation against cholera, covering another year's trial in India, have been presented. On the whole, it seems that the inoculation method does have some protective value, although the facts supporting this view are not yet complete and satisfactory. It is probable that more frequent and perhaps multiple inoculations will be necessary to make the method practically useful; at any rate, enough has been done to justify those in charge of the

matter in urging a further grant of 10,000 rupees for the further prosecution of the work.

Carlsbad.—"To those who have it shall be given." This seems to be particularly true of Carlsbad, which, having got a certain reputation for its waters, and having worked this reputation most industriously and commercially, is now perhaps one of the most prosperous of the German cities which thrive upon invalid visitors. We are told that the total number of patients registered at this resort during the last season was forty thousand. We have as good springs and as good climate in America as at Carlsbad, but the method of life and the system of treatment are the outgrowth of years, and are not so easily imitated.

Perfect Types of Women.—An English surgeon, Mr. Frederick J. Gant, has written a novel called "Perfect Womanhood," in which types of perfect modern womanhood are described. To his mind they appear to be shown in the characters of a trained nurse, a deaconess associate, a female medical missionary, a ritualistic maiden, and a few others. We see no mention of the bicycle girl.

Free Medicine and a Pound of Tea.—There is an enterprising firm in London which offers to its customers groceries and other material comforts, for money, while medical opinions are thrown in for nothing. This, we had supposed, was a distinctly Chicago idea. At any rate, it is rumored that we shall have in this city before long a grand bazaar, run by a Chicago firm, where all kinds of goods will be sold, and where medical men will be in attendance to give free advice to the customers.

Posture in Cycling.—Many physicians prescribe the bicycle, and when prescribing it, give, we have no doubt, the best advice within their light, as to the amount of exercise, the adjustment of the wheel, and the method of riding. A correspondent of the *British Medical Journal*, who claims to be a medical man and a cyclist of twenty-five years' experience, gives the following description of the posture, and the arrangement of the seat and handle bars necessary to correct and healthful riding: "With the laudable intention of gaining an upright posture many riders raise the handles until they are above the level of the seat, or even of the hips, while the seat is placed so low that the knees are never extended. This is a most inefficient and comfortless posture; all control is lost over the machine, and no pulling power obtained for the arms. The arms must be straight and the handles so placed that pulling with the arms shall aid the thrust of the leg without disarranging the steering or shifting the rider on the seat. The seat must be far enough back to maintain a steady hold of the driving (hind) wheel on the road and to place little weight on the front wheel. The following rules apply to normal individuals: The seat should be placed over a point about half-way between the hub and front rim of the hind wheel. The height of the seat should be such that the pedal at its lowest point can be easily reached with the ball of the foot, the foot being horizontal; this means full ankle play. The handles should be as far back as a line passing through the main axle of the driving cog (bottom bracket), the handle bar must be wide enough to clear the thighs freely and to carry the arms clear of the sides. The handles should be at the level of the seat, or at least in such a position that the arms shall be straight downward and only slightly in advance of the body. The point of the handles should reach halfway up the thigh when the pedal is at its highest point, but wide enough to avoid fouling the thighs in steering. The only alteration needed to any modern safety cycle in order to secure these positions is that the handle bar should be some inches longer than the general make. The weight of the body should fall exactly upon the tuberosities of the ischia on the centre of the pads of the seat (Burgess's or similar seat), the thigh not falling to a perpendicular position at the lowest point of the stroke, so that there may be no tendency to slip off the seat forward; the pads of the seat should be well cupped and not tightly inflated. Long experience shows that these points constitute the most efficient, comfortable, and healthy posture in ordinary road cycling. To the racing man or the "road scorcher" no advice is offered.

Translations from the Russian.—We are glad to know that some of our naval officers do good work in addition to their routine service. Surgeon F. B. Stephenson, U. S. N., has lately finished translations from several Russian publications about the gypsy moth, for the State Board of Agriculture of Massachusetts. During a recent cruise on the Asiatic station, Dr. Stephenson made use of his opportunities to advantage in gaining a practical knowledge of the language of this nation, so rapidly growing in strength and influence.—*Army and Navy Journal.*

The Morals of a Surgeon.—What a man does is the proof to the world of what a man is. Many good people fear that the advance of science will bring about the retrogression of morals and religion. We do not agree with them. But if they cannot accept our judgment, let them weigh well a fact like this: Mr. Jonathan Hutchinson, F.R.S., and ex-president of the Royal College of Surgeons, addressed his professional brethren assembled in annual congress the other day, and he thus spoke: "I bore with such equanimity as I could the discovery that I could not compete with my friend in the ratio of successes obtained" (in operations for ovariotomy), "and, acting on the rule of conduct that I would never keep a patient in my own hands if I believed that someone else could do what was needed with greater prospect of success, I gave up doing ovariotomies, both in public and in private, and used to transfer my patients from the London to the Samaritan Hospital." Here is a rule of conduct which has never been excelled in moral worth in any department of professional life or private behavior. A most far-reaching and truly noble rule is this of Mr. Jonathan Hutchinson's; and the fact that he announced it toward the close of his career in the hearing of hundreds of his professional brethren, who are almost as familiar as he is himself with the conduct of his professional life is proof that he spoke mere truth. If these are the morals of men of science may we not say of men of all professions and callings, *O si sic omnes*.'—*The Hospital.*

Society Reports.

THE AMERICAN DERMATOLOGICAL ASSOCIATION.

Nineteenth Annual Meeting, held at the Windsor Hotel, Montreal, Canada, September 17, 18, and 19, 1895.

The President's Address.—The Association was called to order by the President, Dr. S. Sherwell, of Brooklyn, N. Y., who in a brief address welcomed the members from so many distant points of the continent, and congratulated them upon the certain success of the meeting, as promised by the length of programme and number in attendance. He spoke of the limitations of the microscope in settling many dermatological problems, and of the great importance of considering the science of dermatology no less from a clinical and empirical standpoint. He would regard the Association, as it were, a supreme court in disposing of mooted questions affecting the specialist in this country, and would suggest that its most proper work was in the consideration of matters of high scientific interest, rational, academic, and polemic.

A review was made of the speaker's statistical researches into the disparity and excess of the alien element applying for relief at the various clinics of our large cities. The question of constitutional treatment in skin diseases was then discussed. He would not rely upon it wholly, but thought in most cases it was to be employed as coincident treatment along with local measures.

Angiokeratoma of the Scrotum was the title of a paper by Dr. Fordyce, of New York. He described a patient sixty years of age, and showed a colored picture of a scrotum the seat of a great number of dark purple spherical tumors arranged in a somewhat linear manner. They vary in size from a pin's head to several times that size. Pressure causes disappearance of the color in most of the tumors, which are slightly elevated above the surface. Some are covered with a slightly thickened horny layer. No subjective symptoms.

In cases reported chilblains have usually preceded, and the feet and hands have been the parts implicated. Many photo-micrographs were passed showing the histological appearances. The lesions seem to consist of lacunar spaces filled with blood, occupying the papillary portion of the derma. The atrophy of the scrotal skin removing the normal support to the vessels, together with tendency to vascular dilatation as shown by a condition of varicocele present, may, the author thinks, have had an influence in the causation of the tumors. The author's investigations lead him to believe that the primary change is vascular. He upholds Pringle's view that the blood-spaces in the rete Malpighii are caused by a down growth of the cells of the layer, producing a constriction of the terminal loops and their resultant distention. The histological appearances correspond closely with classical cases of angiokeratoma reported by Mabelli and Pringle.

Raynaud's Disease of the Ears was described in another paper by the same author. A man, thirty-nine years of age, with presumable specific history, noticed that the ears became suddenly cold and blue on a warm day and remained so for several hours, gradually resuming the normal color. Such attacks were frequent for about six months, when a portion of the ears remained bluish-black and are so still. The ears feel numb and cold, and sometimes there is a burning pain in them. A gangrenous area formed, having a diameter of half an inch. Cicatrization followed, and the blue color disappeared. Syphilis is suggested as a possible etiological factor; implication of the arterial coats leading to obstruction in the blood-supply, especially when an element of vascular spasm due to cold, etc., is added.

Dr. Zeisler said the clinical picture of angiokeratoma had hitherto not been complete; additional features might be discovered. His own case, which it seemed to him corresponded in every particular with the typical pictures of Mabelli, would seem to differ in features pointed out by Dr. Fordyce. At the same time it seemed to him that Dr. White's criticism is not entirely justified, although he would like to see a little stronger development of the horny layer to deserve that name. It does not seem to him unreasonable that the scrotum should be the seat of keratoma. He believes it may be seen often in cases of varicocele. Wherever the element which favors stagnation of the blood exists, we have an etiological reason for the production of keratoma. The horny layer is so enormously enlarged in every typical case of keratoma, that he believes it to be an essential factor. If he compares a similar case with that of Dr. Fordyce, he thinks in his case the horny layer was five or six times as extensive. That the clinical picture in angiokeratoma is by no means complete, he had another instance within the last two weeks. A man, aged about sixty-seven, called at his clinic. The lesions were on various parts of the body, on the extremities as well as the trunk. They were flat and somewhat elongated angiectoides. During the last few days he had examined the soles of the feet, and on one sole he found two distinct angiokeratomata, corresponding very distinctly with what he had seen before. There was no evidence of the previous existence of angioma. Keratoma should be the essential feature in angiokeratoma, otherwise the title is not entirely appropriate.

Dr. Hyde wished to join Dr. Bowen in congratulating Dr. Fordyce on the excellence of the two photographs. He wished to know if there was any linear arrangement of the lesions on the scrotum, and whether he had any reason to suppose there was any relation between the vitiligo present and the distribution of the lesions on the scrotum.

Dr. Fordyce did not think there was any relation. The linear arrangement, it seemed, followed the course of the vessels of the part.

Dr. Shepherd asked if there was any difference between this and the ordinary varicosity without the keratoma. He had seen a good many cases of varicosity of the scrotum, and in a large proportion of them he had noticed this enormous vascularity of the skin of the part, the veins of which seemed to be generally dilated.

Dr. Fordyce replied that the horny layer of the scrotum is naturally thinner than on the hands, and as this layer is stimulated to new growth by some form of irritation or traumatism, the hypertrophy reaches a greater height in the hands than in the scrotum. The essential condition on which stress is laid by all previous observers is the existence of blood-spaces in the epidermis. He did not think it can be compared to a varix condition of the veins; it was rather a varicose condition of the papillary capillaries. In some tumors the base is cut off entirely, and you have a condition similar to that found in an aneurism, where there is coagulation, deposit of fibrin, etc., in the spaces.

Dr. White said, with regard to the localities here affected, he thinks these do not preclude the idea of Raynaud's disease. He had seen a case of this disease affecting the fingers and precisely this locality in both ears. He, however, had never seen any such affection of the ears alone.

Dr. Sherwell thought that in most of the cases which had come under his observation a history of syphilis was present. He mentioned a very distinct and typical case, which recovered under antisyphilitic treatment, but where the disease recurs from time to time, especially during the colder months, local anæsthesia and a very slight tendency to gangrene on the

tips of the fingers existed, and was aggravated by the cold, and at times the ears were disposed to show similar phenomena.

Dr. Fordyce said Raynaud's original monograph did not discuss the pathological, but simply the clinical, aspect of the cases. Of course, in the speaker's cases there were changes in the arterial coats; but there are many cases of the disease reported by Raynaud himself in which the extremities were free from gangrene. Raynaud's disease, in fact, is a general term, including endarteritis and many other pathological conditions.

Dr. Hyde spoke of a case of lupus erythematosus upon the cheeks of a woman, which rapidly disappeared under ordinary treatment. Almost immediately a typical lichen planus developed upon the extremities. He thought we must enlarge the conditions to which we apply the term lupus erythematosus.

Dr. Fordyce also thought many different conditions had been included under lupus erythematosus. Some were mere localized hyperæmias, some cases disappear spontaneously, while others cannot be made to go away.

Hydroa Æstivale.—Dr. Graham, of Toronto, read a paper upon this subject. Two cases were reported of this peculiar and rare affection occurring after exposure to sunlight. In the first a few small red spots appeared upon the face and hands of a young girl. These recurred as soon as she began to go out of the house, and the lesions became vesicular and pustular. These became black in the centre and umbilicated, followed by crusting and subsequent scarring. No spots appeared on the hands when gloves were worn. At times the face was much swollen.

In the second case a young blond female suffered from burning sensations, swelling, and vesicular eruptions when exposed for twenty minutes or more to the sun's direct rays. Malaise, coryza, sleeplessness, and anorexia accompanied the attacks. In this case, sitting near an open window produced the eruption on any exposed part of the body. On account of the affection the patient has been virtually a prisoner in the house for fourteen years. The skin is at times fissured and scaly as in a chronic eczema.

The term hydroa vacciniforme does not apply to all cases. The author believes that it is not only the ultra-violet rays but also the heat rays of the sun which play a part in producing the affection. The question is how they produce such a deep effect. This is hard to explain without the intervention of the vaso-motor nerves. The inflammation is thought then to be of reflex character. The sun's rays seem capable of producing a dermatitis of variable intensity. The amount of necrosis and subsequent cicatrization will depend upon the vulnerability of the tissues and the amount of exposure. Unlike xeroderma pigmentosum, it does not seem to attack more than one member of a family. A covering to the skin which would exclude the light was almost always effectual.

Dr. Zeisler spoke of a case observed where the lesions recurred frequently on exposure to sunlight. The gentleman had first become aware of the trouble after horseback exercise. He thought the condition one of erythema multiforme and suggested the trial of atropia as a remedy.

Dr. White would also look upon it as a dermatitis rather than as a separate affection to which a particular designation was applicable. No absolute type of lesion is maintained in all attacks.

Dr. Bowen said he had been called upon to examine one such case histologically; the inflammation was here followed by necrosis; the lesions were umbilicated. The microscope showed that the necrosis extended down to the corium. This distinguishes it from erythema multiforme, which is never followed by scarring, as is here the case.

Dr. Hartzell had seen a case in warm weather where the lesions came in the absence of exposure to direct sunlight. The inflammation was not severe enough to produce necrosis. It differed from other cases only in degree of inflammation.

Dr. Phillips, of Toronto, had treated Dr. Graham's case, and on invitation spoke of his treatment, which had been mainly soothing and protective. He thought the ultra-violet rays of light those which produced the effect. He had intended to try their exclusion by covering the parts with bisulphate of quinine in bassorin paste, or to cover the face with some yellow-colored paste.

Dr. Jackson had had for several years a boy under his care at the Vanderbilt Clinic presenting lesions, pittings, and scars of this same affection. He suffered more in winter than summer. This was also the case in Alps-climbers, he believed, in which an English physician, Bowles, had made a successful use of such a brown ointment as actors use.

Dr. Shepherd had within two weeks seen a young lady in Montreal with a dermatitis of three years' duration, which would appear on exposure out of doors, accompanied by swelling, bullous lesions, and subsequent scarring. He had seen it appear in a fellow-traveller in crossing the Alps.

Dr. Allen remembered Dr. Jackson's case, and from having frequently seen the boy, could substantiate the fact of the eruption being at times severe in the winter. He had seen other cases in which the direct sunlight acted to produce lesions on face and hands. From his readings he came to believe the chemical rays responsible, and considered exclusion of light the only rational treatment.

Dr. Sherwell recommended that women so predisposed should always wear yellow veils, and that by so wrapping up the parts as to make virtual developing chambers the disease would be prevented.

Dr. Graham, in closing, said Dr. Bowen's investigations would exclude any idea of the condition being an erythema. He thought the degree of inflammation depended upon the individual rather than upon the length of exposure. Dermatitis solaris would, all things being considered, probably be the best name.

Lupus Erythematosus Disseminatus.—A case of this affection was related by Dr. Fordyce, in which lesions upon the hands and arms disappeared during pregnancy, leaving atrophic spots surrounded by a pigmented zone. In a second case the eruption likewise disappeared, but came back in an equally severe form after the confinement. A large number of photographs were exhibited.

In discussing these papers Dr. Bronson asked if there were sufficient reason for including the second case under Raynaud's disease. He had seen gangrene about the face which could not be accounted for. He always looked for a trace of syphilis.

Dr. White did not think the keratomatous element very marked in Case No. 1.

Dr. Fordyce answered that he would not have called it angiokeratoma if the angiomatous changes were not present. Changes in the epidermis are secondary and the result probably of hyperæmia due to irritation. The changes in the rete were marked.

Dr. Morrow had seen two clinically identical cases during the year. He coincides with the reader's view that they should be called angiokeratoma.

Bromide Eruptions, with a Report of Two Cases.—This paper was read by Dr. Jackson, of New York. After taking bromide of potassium for several weeks the drug was stopped in a young woman, and shortly after this an eruption resembling chicken-pox appeared upon the forehead, whence it spread over the body. Under some of the crusts which formed, especially upon the scalp, there was found a raspberry-like appearance with bleeding points. The case was somewhat puzzling until a second similar case presented itself. The lesions here looked like impetigo conta-

giosa followed by the same wart like lesions. On the legs the lesions broke down into indolent irregular ulcers. This case had been given bromide. The features of interest in the cases is the long period between the cessation of drug administration and the appearance of the eruption.

Dr. Hyde believed that bromide eruptions of this pronounced type occurred chiefly in young subjects and those who were cachectic or below par, scarcely, if ever, being seen in healthy individuals. He had observed quite similar lesions from the iodides, and was prepared to believe that other drugs as well might produce these effects.

Dr. Morrow said children were prone to vascular disorders, and the severe forms of bromide eruption were apt to be seen in them. All our knowledge of drug eruptions opposes the view that lesions continue to appear after the drug administration is stopped. It is difficult to explain why the effect should be prolonged.

Dr. White did not think the general health of the patient had much to do with the determination of a given eruption. It is the result of individual idiosyncrasy. He was not familiar with any other drugs which could produce the lesions described by Dr. Jackson.

Dr. Hartzell recalled the frequency with which valvular heart disease was associated with the severer forms of bromide and iodide eruptions.

Dr. Fox said some syphilides in children resemble closely the bromide eruptions. Mistakes are likely to occur when bromides are being administered to children known to be syphilitic. The drug, too, may tend to bring out as it were the cutaneous syphilis.

Dr. Graham spoke of cases in which a history of bromide administration is hard to obtain, thus leading to doubt.

Dr. Allen said that at times the large bullæ of iodide origin assumed a fungating appearance closely simulating the bromide. He had seen the eruption in an epileptic girl persist for weeks after the drug had been stopped. When an eruption follows a minute dose, as seen from quinine, nerve influence rather than skin irritation due to elimination is to be looked for.

Dr. Sherwell said that dermatological knowledge had advanced, for whereas some years ago such a case as described might be called yaws or something of the kind, now the true nature is generally recognized. Still, cases are seen by him now and then, surely due to the iodides, which are practically bromide eruptions. He had seen the eruption become intensified several weeks after the drug had been stopped.

Dr. Hyde said he had no direct positive knowledge that other drugs would produce these same effects, but such had been reported to him by fellow-practitioners. He mentioned hydriotic acid as such a drug, and thought there might be others.

Dr. Morrow could see no reason why an eruption due to a drug should continue to appear after the drug is withheld, and he considered the histories of cases in which this is reported as generally too vague. Long-continued administration is usually necessary to bring about the required changes of nutrition in the tissue.

Dr. Hyde, while admitting that most drug effects upon the skin quickly subside on stopping the injurious agent, still this particular one did not and should be placed by itself. That children to whom bromides are given are usually in some way out of health, is shown by the very fact of the drug being required.

Dr. Jackson said he had seen bromide lesions persist for weeks after the drug was stopped in a patient he had treated since writing his paper. It was the old lesions which refused to disappear rather than the development of new.

Value and Limits of Usefulness of Electrolysis in Dermatology.—The afternoon session opened with a discussion on this subject. Dr. Zeisler being called upon, said he thought not much that was new could be said upon this subject, and probably the best form for the discussions to take was the recounting by the members of their individual experience. In hypertrichosis, electrolysis was of all means the best treatment; but he thought it was most useful in dealing with stiff hairs, and should not be employed for lanugo. His experience had caused him to look upon it with hesitation as a means of remedying congenital and angiomatous nævi. Its use here he considered limited to small nævi in infants. He mentioned a case of a lady with a nævus covering one side of her face—it was superficial, with the blood-vessels chiefly on the surface. After fifteen or twenty sittings it did not appear to the speaker that the results were very brilliant. He then requested the patient to desist for a few weeks, when the results were found to be very encouraging. Electrolysis was also useful in small growths of the nævi fibromatous types; here, however, a little more care should be taken in piercing with the needle, as scars are apt to remain. He thought the needle should be inserted in such a way that the action would not be too deep, as he preferred repeating the operation to running any risk of scarring. He used the electric needle also in xanthomata. He thought it one of the safest, but not the least painful, methods for this purpose, especially of operating near the eye. As to a local anæsthetic, he had not much faith in cocaine in such cases; the only way he used it was to impregnate the electrode with the drug and render the whole area anæsthetic.

Dr. White agreed in the main with Dr. Zeisler's remarks. He, however, did not recognize the impossibility of removing lanugo hairs; he had done so a number of times. As to the desirability of doing so, that was another matter. He had only operated on occasions where much pressure had been brought to bear upon him. He did not think electrolysis suitable for large nævi with hypertrophied vessels; you may be able to remove the latter, but the work is very tedious, requiring a great many sittings. As to port-wine mark, he had been very unsuccessful, save when the area affected was very small; and he thought it an operation that should only be undertaken under great pressure. Relative to anæsthesia, he had been using a twenty per cent. alcoholic solution of cocaine and he believed it helped to a certain extent. He did not believe there was much absorption by the skin, but a penetration of the drug into the hair-follicles. He did not claim that total anæsthesia followed; but he was satisfied that there was something more than the moral influence of the application to account for the lessened sensation.

Dr. Morrow's experience corresponded with that of the other two speakers. Relative to anæsthesia, he wished to say that some years ago he had experimented a good deal on the practicability of rendering certain limited areas of the skin anæsthetic, and he found the most thorough method to be that of kataphoresis. By saturating any porous material with cocaine an absolute anæsthesia might be obtained over an area corresponding to the surface of a small electrode covered with it. He found that, in those cases, by scratching the surface just enough to break the epidermis without causing exudation, the kataphoric action was very materially favored. He thought there could be no doubt whatsoever of the efficacy of this method.

Dr. Hyde's experience led him to believe that the attempt to remove the fine, downy hairs only stimulated these to greater activity of growth. He mentioned the class of young Jewish girls with heavy black eyebrows and abundant hair of the scalp as one in which he had often found this to be the case. Electrolysis he believed useful in spider-cancer, with small telangiectrodes, and in rosacea where the same condition exists. The operation was useful in the case of smaller vessels, but unsatisfactory in large. Although forced to employ cocaine and other drugs of that nature in cases of severe pain, he had a strong objection to doing so, as he found they had a tendency to cause dermatitis. As

to contagious mollusca he never used electricity, finding them much more easily swept away with the curette.

Dr. Fox thought there could be no doubt of the value of electrolysis in dermatology, the only question to consider was as to its limits. In hypertrichosis he thought it was not only the best but the only means for the permanent removal of hairs, although often a tedious operation. As to the finer hairs, he believes if they can be seen they can be removed ; but it is astonishing how much worry a few scarcely perceptible hairs on the chin will give some women possessed of far more serious facial blemishes ; and consequently he made a rule never to operate upon hairs that were not conspicuous. His opinion is that the effect of electrolysis, if it has any effect at all, is to lessen the growth of hair upon the face. He does not believe that anyone can prove that the removal, either by pulling out, by cutting, or by electrolysis, ever affected the growth of neighboring hairs. As to the painfulness of removing hairs by electrolysis, his experience leads him to believe it is not more painful than the filling of teeth, which, we know, is at most only uncomfortable. Of course if the needle were not properly introduced it might be very painful ; it should never be jabbed into the follicle. As to the other uses of electrolysis he thought too many claims had been made. Excellent results might be obtained in nævus pilosus. In vascular nævi his results have not been satisfactory. In the very pinkish wine-mark he preferred dotting the surface with carbolic or nitric acid ; but in the dark slate-colored wine marks he believed single or multiple electric needles the best. In xanthema he thought he had brilliant success with electrolysis, certainly better than could be obtained with the knife. He doubted if true keloid could be removed by electrolysis. In some cases resembling keloid, following syphilitic ulceration of the cervical glands, where large bunches existed, a very good-looking cicatrix was produced by the use of electrolysis. In angioma he thought it could be used with success, but not with more than that obtained from other methods. He recently removed from the forehead of a child an angioma the size of a chestnut by electrolysis. He used it in one case of epithelioma of the lip with good success. One should not attempt to use it as a cure in very many skin diseases.

Dr. Bronson thought that most of the members knew the advantages and disadvantages of the process ; as to its limits, that was for time to decide. He thought its chief use was in cosmetic operations. The chief disadvantages are pain, the fact that the neighboring hairs sometimes appear to be stimulated, and the danger of producing scars. In some measure he thought these disadvantages might be overcome. Pain, he thought, rather insignificant. In his experience it was the physician, and not the patient, who was apt to cry "Hold, enough." As to the increased growth of the hair, he thought such undoubtedly occurred in many instances. Lanugo hairs he regarded as microscopic hairs, invisible to ordinary eyesight, and as such impossible to remove ; but such was not the case with the finer downy hairs which, after removal of their darker and stiffer fellows, were apt to suddenly take on similar characters ; and it was by the total removal of these, as well as the larger ones, which he believed insured the success of the first operation. Something should be done to avoid the resulting inflammation which rendered the patient so unsightly for a few days. He had been trying the paste recommended by Unna (ichthyol, gr. xx. ; starch, gr. xx. ; albumin, gr. j. ; water, ℥ xxx.), which painted on at night seemed to limit the reaction. He found it succeeded in rosacea after the use of ichthyol, resorcin, and multiple scarifications had all failed. By making multiple punctures as close together as possible, after the removal of the hairs, a considerable blanching of the skin resulted from destruction of blood-vessels, and permanent benefit followed. He also found electrolysis useful in hypertrophied cicatrices.

Dr. Hertzell thought there was very little use in dermatology for electrolysis beyond its application to cosmetic operations, such as removing superfluous hairs, small telangiectodes, etc. He, however, agreed with Dr. Bronson in thinking it of value in rosacea, and believed that here it not only destroyed the larger vessels, but the cicatrices, following the multiple punctures by contracting, and served to drive the blood out of the part.

Dr. Jackson thought the question as to the cause of an increased growth of the hair a difficult one to decide. He looked upon the superficial facial hairs in young women as corresponding to the beards of young men, in whom fresh hairs keep appearing until adolescence, and it was only reasonable to expect the same condition in young women. There may be some increased growth after the operation, but these hairs would grow anyhow. Relative to scarring, he believed there were some women's faces where, do what one might, it was impossible to avoid it ; and he consequently thought it a wise rule never to commit yourself to a strange case by promising that no such effect should ensue. It is especially apt to occur about the corner of the upper lip. The chief difficulty he found about the finer hairs was that of telling when they were really removed and not broken off. He had often noticed pigmentation follow the removal of hairs. As to the question of pain, when patients complained of it, he employed cocaine. Recently he had been dipping his needle in a lanolin preparation of cocaine before each puncture, and it seemed to help. He would be glad if someone could tell him how to reduce the reactionary inflammation. He used to try hot water, etc., but without much apparent benefit. In vascular nævi he found linear punctures with a single needle of value. Before commencing he takes a fine pen and dots the area he intends to operate on. There is no doubt about its efficacy in reducing the color ; the art comes in in knowing when to stop, to avoid leaving a blanched instead of the red tint. Even in cavernous nævi he believes much good can be derived from this treatment ; he has seen some of the large spaces shrink up into a fibrous nodule. In rosacea he thought there was a tendency for the vessels to reappear ; in general redness of the skin he preferred linear scarification. He considered kataphoresis as a very painful method of inducing anæsthesia.

Dr. Morrow thought Dr. Jackson's experience with kataphoresis must have been due to his using currents of too great strength.

Dr. Wigglesworth admitted the truth of Dr. Jackson's remark concerning the futility of treating the large deep vessels in rosacea by electrolysis, he also found that such were pretty sure to grow again. In the case of superficial vessels, however, it is otherwise, and he had often succeeded admirably. In lupus erythematosus one will also get results quite as good as those obtained by incisions. He also found electrolysis successful in treating acne indurata. He thought the best way to use cocaine was in a ten per cent. alcoholic solution, which, lightly applied to the parts, gave the anæsthetic effect of the cocaine as well as the cooling and sedative effect of the evaporating lotion. He thinks it should not be rubbed in, as this made matters worse by increasing the blood-supply. He thinks port-wine marks are often aggravated by wrong treatment ; one case in which a small mark had been made a very large one by the use of potash, under his care, yielded to electrolysis entirely at one sitting. The current used was ten cells, and the punctures were made around the entire surface. In these rapidly acquired conditions, the results were much better than in the old solidified port-wine marks of birth. As to scarring, he managed to avoid it by paying attention to the points already alluded to by previous speakers. The

mistakes made were in using too strong currents, not looking out for idiosyncrasies, such as a tendency to the formation of keloid, or to the development of pigmentation.

Dr. Graham wished to know if any of the members had ever used electrolysis for the removal of hairs in obstinate sycosis.

Dr. Robinson's experience was that the irritation caused by the introduction of the needle certainly produced an increased growth of the neighboring hairs. He instanced the case of chronic dermatitis of the scalp, accompanied by a great stimulation and exfoliation of the corneal layer of the epidermis; when cured this is followed by an abundant growth of hair. The same is seen in fracture of the tibia when the skin is near the broken bone; hairs develop in increased quantities. Shaving is another instance of irritation increasing the growth of hair. For these reasons he never used electrolysis on any part, such as the upper lip, where the hairs are close together; but he thought it was very useful in other parts of the face. Electrolysis is, he thought, the most satisfactory method we know of treating hairy nævus; it sometimes required a great number of sittings, but success is always the reward. In regard to the reactionary inflammation, he thought the method of using the needle had something to do with it; he found that if you go right into the follicle the irritation is less than if you go outside of it. He uses powerful spectacles, which enable him to see every follicle opening.

Dr. Allen had seen quite a number of cases during the summer in which he used electrolysis, and had been using a flat needle with rather sharp edge, carrying it gradually from one side to another at the base of the growth, especially in moles and warts. He generally succeeded in removing these in a single sitting. This he found the nicest and neatest way to get rid of them, and preferable to leaving them after the operation to dry up and fall off. A ten per cent. watery solution of cocaine will render some warts a great deal less sensitive to the pain. He had removed several large moles lately with good results, and knew of no other method where they could be removed without scarring or with so little pain. Electrolysis was especially useful in removing hairs from the chin, and it was not so successful in those of the upper lip. He did not think it was wise to operate on every case that presented itself. Many of these women have morbid notions as to the extent of their disfigurement, and if one operated they might not find the improvement as marked as they expected. Many of these little abnormalities of the skin of the face really enhance the beauty of the individual, and by telling her so he found it possible to reconcile many ladies to their supposed blemishes. He gave an account of two such instances recently occurring in his practice. Electrolysis he had found useful in superficial varieties of port-wine mark, and in such he found the best results were obtained when the needle was used quite superficially. The lanugo hair follicles mentioned, it seemed to him, were scarcely to be spoken of as follicles, being merely superficial indentations of the skin, and care should be taken not to cause the needle to penetrate too deeply. He did not think it was so important to find the opening as to tell the exact direction the follicle took. Glasses would not help here. He did not think the deep effect of cocaine necessary, since it was only the entrance and exit of the needle that caused pain at the surface. For the reactionary inflammation he applied some sedative or used a benzoated collodion or protecting powder for this purpose, but never vaseline or ointments.

Dr. Fordyce had, during the past year, discarded batteries altogether in favor of Edison's current from the street, with which one can get a current as low as half a milliampère.

Dr. White called attention to the comparatively few years after Dr. Hardaway first brought this operation to our notice, that all its advantages and disadvantages were known. It seemed to him that they had stopped there, as there was nothing said to-day that was not known years ago.

Dr. Zeisler thought members should be more guarded in their statements about the increased growth of hairs; he did not think that was true so far as the development of new hairs was concerned. A little stimulation may assist hair already present to grow more rapidly, and he thought that was the most that could be said.

Dr. Hyde, in answer to Dr. Zeisler's remarks, wished to mention a case in his experience which he felt sure could be corroborated by other members present. A man with an obstinate neuritis over one scapula which he had been blistering and stimulating continually for years, had over the affected region a growth of hair two and a half inches long, and nowhere else in that locality. A little downy hair can be produced on the scalp by irritation or stimulation, which, however, will soon be lost again.

Dr. Sherwell, while fully agreeing as to the propriety of using electrolysis in hairy moles, as a general remedy in dermatology, has been much disappointed in it. He has never seen much good following its use in serious angiomatous conditions: there, he found the galvano-cautery or the igneous puncture to give more satisfactory results. His practice was to scoop out small growths or make an elliptical incision, the cicatrix following which is small, often scarcely perceptible, and the result is usually good. As to the use of electrolysis in hypertrichosis, he thinks its achievement does not excel that of the American Indian in his practice of self-epilation. He is accustomed to extract the hairs from the face, and performs it most thoroughly. They keep their faces bare by simply pulling out the hairs. He has recommended a similar course to many people with hypertrichosis, and he has been well satisfied with the result. He believed the continual plucking finally destroyed the follicle.

The Epitrichial Layer of the Epidermis and its Relationship to Ichthyosis Congenita.—Dr. Bowen, of Boston, read the paper. Attention was called to a well-marked layer of cells in the epiderm of embryos, forming a distinct membrane covering the hairs, in certain lower animals. In man this layer has not received recognition. The reader's attention had been directed to the subject by the observation of Dr. C. S. Minot, that certain shreds of fœtal skin contained a layer of large polygonal cells, with a granular body in the centre, and within this a nucleolus. He thought these cells a part of the epitrichial layer described by Welcker in 1864, and since forgotten.

The reader of the paper has found that in embryos of from two to three months the epidermis has an outermost layer of large nucleated polygonal cells of peculiar shape. In the sixth month this layer has disappeared over most parts of the body. The resemblance of this layer of cells to the epitrichium covering the hairs and the epitrichial layer of certain animals makes the author conclude that they are homologous structures.

A case was related of a child born with a thin, perfectly smooth, membrane completely covering it, and closely adherent, suggesting a paraffine-paper envelope. This began to peel off after five weeks in large strips, leaving normal-looking skin. There were no fissures as in ichthyosis. This condition seemed to be due to the persistence of the epitrichial layer, and the author believes that similar cases reported by Hallopeau, Grass, and Török belong to the same category. Instead of gradually exfoliating and disappearing by the seventh fœtal month the epitrichial layer retains its integrity. The true horny layer underneath desquamates in small scales after this covering is removed.

Dr. White, referring to the desquamation of the early formed hairs which takes place in utero, wished

to know from Dr. Bowen if he had noticed whether or not they were connected with this epitrichial layer, or whether they penetrated deeper and were a part of the composition of the fœtus.

Dr. Bowen, in answer to Dr. White, said, in the animals experimented upon the hairs were all underneath the epitrichial membrane, which was situated outside them. In man the hairs do not appear until after this membrane was lost, at least not to any extent.

Statistical Report.—Dr. Hyde, of Chicago, reported for the Committee on Statistics that during the year the total number of skin cases reported by members was 24,321. No cases of scleroma neonatorum, rhinoscleroma, pemphigus neonatorum, anthrax, myoma, pellagra, nor impetigo herpetiformis have been reported, while of eczema there were 6,270 instances. Syphilis gave 2,452, and acne 2,261. About one-eighth of all cases (3,107) were of the rarer cutaneous affections.

A Remarkable Case of Purpuric Eruption Ending in Gangrene and Apparently Caused by Sodium Salicylate.—Dr. Shepherd, of Montreal, presented a paper on this subject. A patient in the Montreal General Hospital suffering from a swelling of the knee, due to acute synovitis, was given three twenty-grain doses of salicylate of sodium, when an urticaria-like eruption appeared and soon became petechial. These lesions were followed by deep sloughing, leaving ulcerations slow to heal. The upper portion of the body, especially the region of the shoulders, was mostly affected. There was also an eruption in the pharynx and larynx leading to œdema and alarming symptoms. The eruption disappeared only after thirty days. In some instances the whole spot became dark from infiltrated blood, and at times the whole body was covered with coffee-colored spots; some disappeared, going through the various color-stages of a bruise. Local gangrene occurred, especially over the shoulders, but also in the mouth and pharynx. About the shoulders gangrenous areas, ranging in size from a fifty-cent piece to that of the palm were seen (these were well shown in the photographs). During the separation of the sloughs there was a rise of from two to three degrees of temperature. The patient was presented at the meeting and showed extensive red cicatrices in the regions where sloughing had taken place. A small ulcer on the right arm still remained.

Dr. Elliot thinks that it resulted from the administration of the sodium salicylate, and he does not think it a manifestation of peliosis rheumatica.

Dr. Buckley never remembered a lesion of peliosis rheumatica where the lesion broke down, whereas in drug eruptions we have sloughing. In the absence of any other explanation he inclines toward the opinion that it was artificial and produced by the sodium salicylate.

Dr. Bronson thought the diagnosis should be a composite one, partly peliosis rheumatica modified by the use of the drug salicylate of sodium. Peliosis rheumatica never, as far as he knows, causes gangrene.

Dr. Robinson was not prepared to state the cause, but does not think it a case of peliosis rheumatica, which he considers incapable of producing such a condition.

Dr. Graham thinks it may be of a rheumatic character. Although the germ has never been isolated, we know that rheumatism is an infectious disease. Some of the most extraordinary symptoms result from it, profound nervous trouble, hyperpyrexia, etc. It is therefore possible that some such condition as this might be produced; or in conjunction with the rheumatism we might have some other non-detected organism present as a cause.

Dr. White said we have to consider the affections it most closely approaches, not what it is. One might think of three affections in connection with these symptoms: 1. Peliosis rheumatica, but the distribution and outcome of the disease are entirely at variance with the affection. 2. Drug eruptions. As these have no bounds set to them, and our knowledge of them is at present very limited, it would be unwarrantable to conclude that they might be manifestations of salicylic-acid poisoning. Any of these cases of salicylic-acid irritation of the skin which he had seen, never approached anything like this in severity. 3. The next affection to be considered is rare: hemorrhagic form of dermatitis—dermatitis multiform or herpetiformis. The early urticarial nature of the lesion, the vesicular, bullous, and hemorrhagic varieties are all within the limits of this affection. The only objections against it are the gangrenous and necrotic condition at the end of the process. Were it not for the symptoms of synovitis, etc., preceding the exhibition of the drug, he would have been inclined to favor the drug as a cause of the eruption.

Dr. Morrow thought it impossible to determine the precise etiology of the eruptoin. He was inclined to look upon the sodium salicylate as the causal factor here, and the unusual character of the eruption as due to the peculiar constitution of the patient.

Dr. Allen had seen some severe cases of eruption after salicylates in rheumatic patients, but never anything equal to this; still he could hardly doubt the causal action of the drug.

Dr. Klotz did not see that the presence of gangrene should exclude the possibility of peliosis rheumatica; we have hemorrhage in the latter disease, and, given hemorrhage, it is only a question of intensity whether or not gangrene will follow.

Dr. Shepherd only began to doubt the sodium salicylate as a cause when he noticed crops of the eruption continuing to appear after the stoppage of the drug. Then the eruption was preceded by the rheumatic pains. Then the eruption seemed to be incompatible with such a small quantity of the drug as had been given (only four doses, amounting to about eighty grains). He had never seen a case of peliosis rheumatica become gangrenous, but he quite agrees as to its only being a matter of intensity. Hutchison reported a case of purpura thrombica which resembled this one.

Mycetoma of the Foot.—Dr. Hyde, of Chicago, read a contribution to the study of mycetoma of the foot as it occurs in the United States. The patient described was born in America, of Bohemian parents, and had never travelled out of his native State. The disorder began thirteen years ago, at the age of seven. He was in the habit of wading in the river near his home in Iowa. A hard nodule first appeared within the skin of the footsole, and gradually spread until the anterior third of the foot was extensively involved. The diagnosis—tuberculosis and sarcoma—had been made by various physicians. The feature was fungoid projections from irregular surfaces of infiltration. A central canal perforated the axis of each tubercle, often blocked by flabby granulation. Examination showed granulation tissue with a considerable number of giant-cells in the derma. Nothing resembling the "clubs" of other observers were found.

Madura foot is apparently a local disorder. The differences between the fungus of mycetoma and that of actinomycosis is that the latter grows readily in a hydrogen atmosphere and the former with much greater slowness. They differ also in the rapidity with which they take up aniline stain. There is no agreement as to what constitute the differences between the white, red, and black varieties. In some cases, where fish-roe-like particles have been surgically evacuated from sinuses existing in unquestioned subjects of madura foot, no fistulous tracts have opened externally to the outer surface of the skin.

The author concludes that there are clinical symptoms of mycetoma which are to be recognized in some cases and not in others. Unquestioned instances are on record where none of the usual features was exhibited. The constant symptoms are practically reduced

to a characteristic deformity of the affected part, prominently the foot, but also the hand, knee, and a few other regions. There is a history of slow involvement of tissues. There is a notable absence of pain and of complicating accidents, such as erysipelas, eczema, etc. The separate vegetable fungi are set in granulation or necrotic tissue, with a number of unusually large giant-cells, which seem to be exercising a phagocytic effect upon the intruder. In a well-marked case there is usually a central body, made up of semilunar or reniform bodies, traversed by a net-work of mycelium.

Conclusions.—There are clinical symptoms of mycetoma which are to be recognized in some forms and not in others. These may be termed non-essential features of the malady. They are: 1, The appearance of blackish or reddish granules of pigment, free and within the cells furnished by the secretion; 2, the discovery of particles resembling the roe of fish, either expelled from the sinuses or imprisoned within the unbroken surface of the skin; 3, the occurrence of sinuses leading from without inward as far as muscle, tendon, or blood-vessel. Cases of unquestioned mycetoma are on record where none of these features are exhibited.

Dr. Elliot wished to know whether Dr. Hyde made an absolute distinction between the fungus that caused madura foot and that recognized as the cause of actinomycosis.

Dr. Hyde, in reply, said he was not justified in drawing any conclusions from his observations on this case. But from Indian observations and his experience in this case combined, he was inclined to think that there were probably several varieties of the ray fungus, and that the variety causing madura foot was not identified with that causing actinomycosis. He thought there might be an American variety of the ray fungus which caused mycetoma.

An Etiological Puzzle.—Dr. White, of Boston, Mass., in this paper described a tuberculosis of the skin of the hand in a young girl who had been accustomed to wash the handkerchiefs of a parent who died of phthisis—the patient was beginning to develop the same disease herself. Another case came to the clinic with characteristic tuberculosis of the lobes of both ears gradually coming on for eight years. The ears had remained long inflamed after piercing for earrings and never healed. The woman who bored the ears died soon after of consumption; the sister who dressed the ears died also of the same disease. The operator may have wet her needle or end of the silk in the mouth, or subsequent dressings may have caused the infection, or bacilli may have entered through the medium of the air. The puzzle is which was the case.

Dr. Shepherd thought the first explanation of wetting the fingers a correct one.

Dr. Fordyce's last case of tuberculosis cutis was in the finger of a doctor who had used this finger when percussing. A couple of years previously bacilli were found in his lungs, and it was always a question to the speaker as to whether the bacilli were derived from the lungs or whether they appeared independent of the lung lesions by the irritation of the part.

Dr. Hartzell had a tubercular case of undoubted local infection. The child's father had recently died of consumption (three months previously). The lesions on the child were, one at metacarpal joint of the thumb, one upon the knee, and another upon the opposite leg—in fact, in just such situations as a child exposed to tubercular sputum could become infected when crawling over the floor. The suggestion was obvious.

Dr. Graham recounted the history of a case of a young lady patient of his, affected with phthisis. She was nursed by her mother, who, contrary to instructions, washed the handkerchiefs, etc., used by her daughter in expectoration. She developed several tuberculous sores about the knuckles, and three or four months afterward also developed phthisis.

Unique Case of Agminate Folliculitis of Parasitic Origin.—Dr. Hartzell, of Philadelphia, read the paper. A man aged thirty-two presented two varieties of lesions on the leg belonging to some morbid process: an oval elevated patch covered with scanty crusts over a bright-red, uneven granular surface; smaller patches closely examined were seen to be made up of swollen and inflamed hair-follicles. There were also pin-head to pea-sized pustules in groups and singly. The primary lesions were pustular and increased the patch by appearing at the periphery; some furuncles formed. Examined portions showed a small cavity surrounding the hair in the upper part of the epidermis; a few spores and mycelial threads. The rete was thickened. The follicles were enlarged and distorted. In some sections were grape-like clusters of spores attached to mycelium. The fungus presented larger elements than are usually seen in tinea circinata. Under sulphur improvement began at once, but the disease had existed for about ten months, incapacitating the patient for about half the time. Contact with animals as a source of infection could not be made out. The author believes that the agminate folliculitis of authors is most probably a deep trichophytosis such as here described. Particular attention is called to the Biondi-Haidenhain stain as applicable for the tricophycton. The case illustrates that the trichophytosis may cause extensive painful disease in other locations than upon the hairy part.

Dr. Wigglesworth wished to ask whether Dr. Hartzell considered there was any relation as to the extent and severity of the lesion and the sources from which it was derived, whether from the horse or some smaller animal.

Dr. White thought we recognized how deeply into the tissues of the skin some forms of trichophyton can penetrate, as seen in kerion, a much more common type of this affection than the agminate forms.

Dr. Hyde had seen a couple of cases of exceedingly severe trichophyton derived from sheep in sheep-shearing cases brought a long distance from the city, and in these cases it had always taken the form of sycosis.

Dr. Fox objected to title of paper, and thought it should have been reported as a unique case of trichophytosis. Most of them had seen these peculiar forms of trichophyton which occasionally develop these small folliculate patches.

Dr. Sherwell at former meetings had spoken of ravages of trichophyton in lower animals. He thought scratching had something to do with the implication of tissues.

Dr. Hartzell, in answer to Dr. Wigglesworth, said he believed the severity of the disease was determined to a very considerable extent by the variety of the plant, but much more by the character of the soil. The fungus, he thought, grew much more luxuriantly in deep cases than upon the surface, and the elements are larger than in the superficial variety. In this case there was a double infection, and he believed to a certain extent in an antagonism between the staphylococcus and the trichophyton. The fungus did not grow at all well in the pustules; but it was found deep down where there were no pus-cells. He called this an uncommon case, because, so far as he knew, no other case of this character occurring in this situation had ever been reported.

Drug Eruptions.—Dr. Fordyce, of New York, read notes on "Drug Eruptions." The speaker referred to the nodular form of iodic eruption in a woman, where the lesions reached the size of the fist, and were not to be looked upon as erythema nodosum. It is probable that all iodic eruptions are secondary to certain vascular changes, and this may account for the exaggerated lesions seen upon a paralyzed member. An-

other case was of a rupia-like eruption due to the iodide of potassium, but simulating syphilis, in a syphilitic subject. The lesions healed under boric-acid ointment. A second case of similar nature showed ulcerations which healed when the iodides were stopped. The lesions in both cases corresponded with the anthracoid variety of iodide eruptions. The cases would seem to show that the skin in some persons reacts to iodide in much the same manner as to the syphilitic process.

A colored plate was shown of an erythematous rash covering the whole central portion of the body as a diffuse, and the other parts as a scattered, eruption, following the use of mercurial ointment. Another case similarly produced was one of erythema scarlatiniforme, which had been taken for scarlet fever. The last case was one of erythematous eruption from the internal use of boric acid given in thirty-grain doses daily for a month; a multiform erythema of the trunk, and a swelling of the upper lids were present. There was also inflammation of the conjunctiva. On stopping the boric acid, the symptoms disappeared. Other cases have been reported from this cause, but the author has seen no mention of the hard œdema of the eyelids as seen in his case.

Dr. Jackson related the history of a case in which he had been called in consultation; it was supposed to be scarlatina. Previously had been treated with blue ointment. He found patient with no fever or any other clinical signs of scarlet fever except the rash; decided case was not scarlet fever, but one of scarlatiniform rash from mercurial ointment.

Dr. White thought it had been occasionally observed that the use of stimulating applications to the skin was capable of lighting up widely spread dermatitis conditions. He had seen two cases of boric-acid eruptions.

Dr. Klotz had recently seen a case of fatal poisoning following use of boric acid, which is generally considered an innocent drug. He had seen a dermatitis occur after prolonged use of small doses. In the fatal case death was due to desquamative nephritis, result of irritating action on the kidneys. He thought there was some doubt whether death was due to the poison or to the kidney trouble.

Urticaria Pigmentosa.—Dr. Morrow, of New York, reported a case of urticaria pigmentosa of twenty years' duration, with remarks on dermographism. The case was the first recognized as one of this affection observed in this country. It is unique in being under observation through infancy into adult life. Many cases show a spontaneous tendency to disappear at about the eighth or ninth year. The skin at the present time shows the property known as factitious urticaria, and this has been a constant feature throughout. The formation of figures upon the skin after irritation shows irregular elevation or a beaded appearance, each bead representing the site of a lesion. Quotations were made from an already published description of the case. Lesions suggesting minute pigmentary moles have appeared in recent years, and the large nodular masses formerly present have disappeared to a large extent. There is too much less pruritus than formerly.

It must be conceded, the reader says, that in the clinical course of this disease and in the anatomical changes which it presents, it shows many points of difference from urticaria perstans.

In the present case the sound skin has always been subject to dermographism, although in a less marked degree than the pigmented lesions. It may be questioned whether the urticarial elevations and the pigmented patches are expressions of the same or of different morbid processes. Is there a causal or merely a coincidental connection between them? In the present state of our knowledge it is impossible to give a satisfactory solution of these pathogenic problems. In most cases there is a history of urticarial attacks preceding the appearance of the pigmented patches. The hyperplasia and pigmentation, the author believes, are the result of the intense and more or less constant congestion of the skin from the frequent recurrent attacks. He has always regarded it as belonging to the urticaria group rather than as presenting a distinct type of disease. There is probably, conjoined with a vaso-motor hyperexcitability, a disturbance of the trophic centres which regulate nutrition.

Dr. White believed one of the most notable features of this disease was its more general prevalence in England than in other civilized parts of Europe. The number of cases of this disease recorded in this Association is very small (24).

Dr. Bronson asked Dr. Morrow how long this appearance of factitious urticaria remained, and whether when it disappeared it could be revoked immediately or only after an interval.

Dr. Morrow said the patient was stripped forty minutes Within fifteen or twenty minutes the lines intervening between the lesions would become effaced, and the urticarial elevations still remain persistent. By slightly rubbing the surface these lines had a tendency to reappear. The urticaria on the sound skin has a tendency to disappear in from forty to sixty minutes.

Dr. Bronson said, in a perfectly graphical picture of urticarial pigmentation, there is a striking difference between the distinct lines and these little bead-like elevations. The latter are no more numerous at these points than one would expect from common irritation of the surface. The irritation seemed only to affect the old lesions between them in a common factitious urticaria.

Dr. Allen had had one case of urticaria pigmentosa in his practice off and on for several years. With reference to the rapidity with which the urticarial wheals came out on the permanent lesions, or on the neighboring healthy skin, it often happened that in removing his clothes, or in indulging in a little scratching or rubbing after their removal, there was an almost immediate appearance of plaques as large as the palm, which became diffused over the healthy skin and the dark-brown pigment spots.

Ulerythema Sycosiform.—Dr. Cantrell, of Philadelphia, presented a paper in conjunction with Dr. Schamberg, with the above title. He described a case of the affection to which Unna called attention under the above title in 1889. A man aged fifty-five had suffered in 1886 from a pustular disease of the beard lasting for two years and ending in recovery. In 1891 he again became affected with what seemed to be a non-parasitic sycosis. Two years later a smooth glistening area of atrophic appearance occupied portions of the cheeks, showing complete loss of hair in places. No pustules, but over the area a few vesicles and blebs, which dried into brownish crusts. The affection proved very obstinate, new vesicles appearing every few days. Arsenic aggravated the condition. There is a follicular and peri-follicular inflammation which goes on to destruction of the hair-follicle and formation of atrophic scars. Histologically the stratum corneum and lucidum were missing; the granulosum was well marked. Intense sharply defined cell infiltration, nests with walls consisting of fibres of connective tissue. Cell infiltration most marked around hair-follicles. Overgrowth of connective tissue in papillary layer. Few hair-follicles and no sebaceous glands in section. Giant cells absent. The disease simulates, but is not identical with, lupus vulgaris. No nodules, no bacilli. The writers agree with Unna in considering the condition a distinct entity and accept the name.

Erysipelas.—Dr. Allen, of New York, read a paper on Erysipelas based upon his personal experience in treating fifty cases. He had previously reported fifty others to the Association, and now studied this series of one hundred in the light of the etiological bearing of

preceding skin affections upon the production of the disease, and secondly in regard to the effect of local treatment.

He had found ichthyol the best drug, its combination with collodion the best way to apply it, and strongly advocated the application of the tight adhesive band to check the spread. He explained its action by pressure made upon the lymphatics. Since reading a paper on this subject four years ago, he had applied the band in thirty or more instances, with the result of checking the spread in about half. Many cases recovered under this combined local dressing very promptly.

Dr. Shepherd said erysipelas was a self-limited disease. He had never been able to check its progress by any treatment.

Dr. Fordyce has secured better results from ichthyol than any other drug.

Dr. Zeisler said that in Chicago, where they had separate wards for erysipelas, boric acid had been replaced by ichthyol, which had been found superior.

Dr. White thought extension to the margin of the bands, as advocated by Dr. Allen, would indicate a greater amount of spreading than he would expect to get in his own cases, treated with carbolic-acid solution in alcohol and water.

Dr. Robinson preferred black wash or lead and opium. The latter constricting the lymphatics, and thus opposing spread of the process.

Dr. Bronson used resorcin in strong solution for superficial erysipelas. He also recommended ichthyol.

Dr. Elliot treats a large proportion of his cases with ichthyol solution, but ten per cent. ointment of lactate of lead also acts well. He thought that when recovery was observed in two or three days one must attribute it to the effect of the drug.

Dr. Allen, in closing, said that while erysipelas was self-limited, the limit was too often the death of the patient. There were no deaths in the series reported, but he related two fatal instances in infants. The limitation caused by the strappings he thought significant.

Election of Officers.—*President*, Dr. A. R. Robinson, of New York; *Vice-President*, Dr. F. J. Shepherd, of Montreal; *Secretary and Treasurer*, Dr. C. W. Allen, of New York.

Other papers were read by Drs. Klotz, Elliot, White, Robinson, Zeisler, Bulkley, and Fox, which will appear later.

Therapeutic Hints.

Chloroform was discovered by Mr. Samuel Guthrie, of Sackett's Harbor, N. Y., in 1831, and is produced by action of chlorine upon alcohol.

Alcohol in Liquors.—The average percentage by measure of alcohol (specific gravity, 0.825) of the following wines, liquors, etc., is: Sherry, 19; Madeira, 22; Malaga, 18; Tokay, 9; Burgundy, 14; Claret, 15; Hock, 12; Champagne, 13; Rum, 53; Gin, 51; Beer, 1 to 3; Ale, 7; Porter, 4; Stout, 7; Cider, 7. —Wood and Dunglison.

Convulsions produced by a drug can be produced only in five ways: 1, They may be epileptiform—*i.e.*, cerebral; 2, they may be conceivably due to stimulation of the peripheral ends of the motor nerves; 3, they may be conceivably caused by irritation of peripheral ends of sensory nerves; 4, they may be muscular—*i.e.*, due to a direct action on the muscles; 5, they may be spinal.—Wood.

A Misprint.—We find in one of our contemporaries the following old misprint: "Even nowadays the definition of inflammation: rubor, calor, tumor, et dollar, is worthy of consideration."

This is true. The dollar, however, nowadays comes first.

Tracheotomy.—An incision in the anterior region of the neck causes anæsthesia of surrounding parts, and hence it is only the first incision that gives pain.—Brown-Séquard.

Ascites.—

℞ Potassii bitartratis ..... ℥ jss.
Potassii sulphatis ..... ʒ ss.
Pulveris scillæ ..... ʒ ij.
Antimonii et potassii tartratis ..... gr. j.

M. Sig.: One teaspoonful every four hours until active purgation and diuresis follows.

—Eberle.

The Face during etherization is reddish; marked pallor and lividity are respectively important indications of failure of the heart's action and failure of respiration.—Wood.

Organs of the Neck.—The sensations in the most different parts of the organs of the neck are, as a rule, jointly referred to a region in which, so to say, the joint sphere of sensation (the sensorium commune, according to Zeissl's analogy) of the entire throat is situated. This region is the front part of the neck, the laryngo-tracheal region.—Gottstein.

Intra-cranial Pressure.—The classical symptoms of intra-cranial pressure are headache, vomiting, and optic neuritis.

Surgical Suggestions.

Ganglion.—Inject from five to ten drops of the tincture of iodine into the ganglion. A bandage is applied, partly with the object of exercising pressure and partly of fixing the adjacent articulation. The pain is but slight, and ceases on the second or third day. The cure is usually complete in five or six days. Sometimes a second injection may be necessary on the fifth or sixth day. Recurrence has been known after all the usual methods of treatment; and in one of the author's cases the ganglion had already been twice removed.

—Duplay.

"Peritoneum to Peritoneum."—Some years ago various accidental experiences combined to unsettle my belief in this axiom. During the past two years I have deliberately and intentionally, where possible, acted as if the axiom were an error, and the result of this experience has been to convince me that, for all purposes where sound, speedy, permanent union is desired, the apposition of two intact serous surfaces is a surgical mistake.—J. Greig Smith.

In Syncope during ether narcosis, alcohol should never be used.—Wood.

Dislocations of Clavicle at sternal end, when other means fail to retain bone in place. The hypodermic injection of absolute alcohol is indicated, deep into tissues about the displaced end; this sets up an adhesive inflammation, which retains bone in place.

Sprains of Foot.—Most successful treatment is use of hot foot-baths for fifteen minutes three times a day; follow each bath with massage for fifteen (15) minutes; then apply snugly a Martin rubber bandage from toes up as high as ankle and have patient walk. Ballet dancers use this method with such success that they are seldom incapacitated for work longer than a week.

Rigidity of Os Cervix.—Ten (10) grains antimonii et potassii tartras, dissolved in half tumbler of water; give teaspoonful every ten or fifteen minutes till free emesis. Under proper use of tartar emetic lacerated cervices et perinei will be the exception in complicated cases.

Disinfection of Vaults and Cesspools.—The disinfectant should kill all pathogenic microbes, including the bacillus coli communis and the bacteria of putrefaction.

The best of all disinfecting agents for the destruction of fecal matters in vaults and cesspools is sulphate of copper, employed in connection with one per cent. of sulphuric acid. The quantity of sulphate of copper required is one pound for every three cubic feet of fecal matter mixed with urine. Half this quantity was found sufficient to destroy the cholera bacillus. It was found necessary that the disinfectant should remain in contact with the infectious material for at least twelve hours.—VINCENT.

Correspondence.

OUR LONDON LETTER

(From our Special Correspondent.)

GRIEVANCES OF HOSPITAL NURSES—SEWAGE FLOODING OF HOUSES—NEWSPAPERS ON MEDICAL MATTERS—DURHAM MEMORIAL AT GUY'S—SCARLET FEVER AT BIRMINGHAM—ADULTERATION LAWS—DR. RUFFER—CHOLERA—HEALTH OF LONDON.

LONDON, September 21, 1895.

THE grievances of hospital nurses are once more before the public. All the week the *Daily News* has been inserting letters under the title of "White Slaves in our Hospitals," and a leading article has directed attention to this correspondence. No doubt there is much necessary hardship in a nurse's lot, but this does not excite complaint. It is the unnecessary impositions which become the proverbial straw to the camel. The managers of our hospitals have much of their business to learn and are too apt to take their views from their officials. One committee is in the hands of its secretary, another listens more attentively to the matron. Neither of these should be suffered to usurp the authority of the Board.

Too often the matron rules the nurses and hoodwinks the committee, and her rule is a terrible tyranny. I am inclined to agree with those who think woman constitutionally incapable of just administration, for when she rises to positions of authority over her sisters her yoke is not only heavy, but armed with many tiny teeth to torture the bearer. But to return to the complaints made. Food of inferior quality or insufficient quantity is mentioned. Surely any hospital board permitting this deserves to be exposed, and should not be allowed to plead ignorance. It is true such boards are unpaid, but if men do not attend to the duties they undertake in the name of charity, they cannot escape the responsibility of their neglect. If they let their paid officials blind them it is their own fault. Authority over a great hospital is a position of trust and must neither be abused nor neglected. The question of long hours is not so easily disposed of as that of diet. It is a question of cost, and all the hospitals are crying aloud for more funds. It is true, however, as pointed out by the *Daily News*, that managers are ready enough to spend on extensions and new buildings, and to get up special funds for such purposes, and the public would quite as willingly support a special fund for providing good food, reasonable hours, and comforts for the nurses. That the hours are too long is admitted on every hand, while the many who break down in health offer a standing proof of the wrong that is done them. Unfortunately there has been too much romance thrown round the occupation of the nurse, and many have therefore entered on the calling without proper appreciation of its duties. But this is no excuse for those matrons and boards that have taken money to teach nursing and kept their victims at hard, menial work for hours which no man's trade union would permit, until their health has broken down and they have been told they are unfit for a calling the real duties of which they have not been allowed to attempt. This kind of swindle (for what else is it?) has often been perpetrated on paying probationers, and should be made impossible in the future. If a man pays a premium to apprentice his boy to a trade the master is bound to teach the trade, and a "paying probationer" expects to be trained in nursing—not in menial work, which she can learn at home.

The water famine in East London is not the only sanitary danger that has lately been prominently before the public. Westminster has been suffering from sewage overflowing into cellars and basements, and strong representations have been made by the magistrate to the local authorities on the urgency of the case and the necessity of immediate action. It seems surprising that most of the property involved belongs to the Ecclesiastical Commissioners, but I suppose it is let on long repairing leases to tenants who let to others, and these in their turn underlet, so that it is not easy to fix responsibility without full inquiry. Our leasehold system has other disadvantages besides those relating to sanitary responsibilities, but the latter are enough to make the cry for easy enfranchisement reasonable. Neither leaseholders, freeholders, nor Ecclesiastical Commissioners are solely concerned. The County Council has some authority, and one of our medical officers of health, some years ago, reported to his vestry on the "Sewage Flooding of Basements Due to the Inadequacy of Main Sewers Vested in the London County Council." It would be interesting to learn what became of that report, though the attention of the Council has been repeatedly called to the matter from other sources. No doubt something must eventually be done, and it would be well for experts to inquire what can be done to abate the recurrent nuisance.

Some allowance for the dead season must be made for the newspapers which have ventured in search of copy into medical pastures. The *Chronicle* is a well-conducted daily which does not often commit itself so much as it has done anent the report of the Local Government Board. Such blue books are very properly noticed by the newspapers. In fact, one of the chief uses of these reports is the circulation of careful abstracts of their contents. Criticism of such productions, to be admissible, must be thorough, and the popularization of such reports by abstracts in the newspapers is perhaps the best use to make of them. The *Daily Chronicle* has, however, ventured to remonstrate with the chief medical adviser for devoting so much energy to the study of bacteria, rather than to the routine of administration! Such a complaint as this in our influential organ must surely be attributed to illness or absence of the generally judicious editor, who would scarcely have allowed an article to appear stigmatizing bacterial investigations as the outcome of "freakish theory," and seriously urging the authorities to "banish the microbe curators to an attic not required for other purposes!" I hope the editor was only absent, not ill, or if the latter, that the indisposition was not mental.

It is proposed to endow in perpetuity two beds at Guy's Hospital in memory of the late Mr. Durham. A sum of £2,000 is being asked for to endow these "Arthur Durham beds."

Birmingham has suffered from a sharp epidemic of scarlet fever, which the Medical Officer of Health hopes has reached its highest point and will now decline. At the close of last month there were four hundred and sixty cases under treatment. Cases have been received from all districts of the city, so that the disease seems widely diffused.

The Select Committee on the Adulteration Laws has reported to Parliament the evidence taken, and asks to be reappointed next session in order to complete its work. It has obtained through the Board of Trade a *précis* of the adulteration laws of other countries, which will prove a valuable work of reference to many.

I regret to say that Dr. Ruffer's attack of diphtheria

has been followed by paralysis, so that he will not be able to resume work for some time.

Cholera having reappeared in Europe, cases of diarrhœa at Grimsby and other ports are being anxiously watched lest early cases of the epidemic should be overlooked. The tendency to recrudescence is not forgotten, and the sanitary department seems to be active, so that we may escape serious invasion, although a few isolated cases may occur.

The health of London and the Provinces continues to be satisfactory, and the death-rate is generally low.

ALKALINE INJECTIONS IN GONORRHŒA.

To the Editor of the Medical Record.

Sir: In reference to the discussion of alkaline injections in gonorrhœa, I beg leave to call attention to the following extract from an article of mine, on the pathology and treatment of that disease, which appeared in the Atlanta, Ga., *Medical and Surgical Journal* for August, 1894.

The treatment of gonorrhœa is a matter of importance to every surgeon, for, like the poor, we have it with us always. A few points must be borne in mind. The first is that we have a narrow tube filled with a muco-purulent secretion, not readily miscible with water, and behind this liquid plug is a sphincter muscle closing the channel. If an injection be made, it will but play on the end of this plug, and will not affect the portion of the urethra in which the seat of the disease lies. Again, this secretion is actively contagious, and if forced into the bladder, will extend the disease to that organ. It is therefore necessary to remove the secretion from behind and treat a clean membrane.

This may be done in several ways. If the patient be told to urinate immediately before the treatment is to be administered, the urethra will be fairly clean, but irrigation is far better. A small flexible catheter, lubricated with glycerin, may be introduced into the triangular ligament, and a warm solution of sodium bicarbonate run through it, washing the urethra as it returns. From a pint to a quart will suffice, and the whole quantity of pus will be dissolved by the alkaline bath, and will be entirely removed. By raising the fountain-syringe containing the soda solution, any desired pressure may be obtained, and enough pressure should be used to dilate the urethra sufficiently for the wash to reach the bottom of the crypts.

The use of the glycerin is very important, for if any oil be employed, the urethra will receive a waterproof coating which will defeat the treatment, and if corrosive sublimate be applied to the tube coated with albuminous muco-pus, the resulting precipitate affords an impenetrable covering for the gonococci.

Lynchburg, Va.

THE ABUSE OF MEDICAL CHARITY.

To the Editor of the Medical Record.

Sir: The article by Dr. Van Fleet on the Abuse of Medical Charity, in a recent number of the Medical Record, ought to be of interest to every physician practising in the larger cities where hospitals and free clinics abound.

From personal experience in dispensary and hospital work, it seems to me that the time has arrived when every physician should give this subject serious thought and use his best endeavors to prevent this wholesale abuse of medical charity. Dr. Van Fleet has offered some valuable suggestions, and it would undoubtedly be well to hear from other gentlemen who are working in the free clinics. Another suggestion, which is not original, is for the applicant to obtain a note from a physician living in applicant's neighborhood.

Of course, any suggestion made is only for those clinics which attempt to prevent this abuse, and I regret to say that there are some which do not attempt to prevent it, but seemingly encourage it. In this respect I have in mind the New York Hospital Dispensary, where patients are treated for a dollar per month, medicine extra, doing away with any idea of pauperism, and unless the method of investigation of applicants has recently been changed, it is a very lax one.

At St. Bartholomew's Dispensary the applicants are hardly questioned as to their financial resources. As in many other clinics, a very large percentage of patients attending here can readily afford to pay moderate fees for treatment.

Last, but by no means the least, is the Vanderbilt Clinic. There is now, I believe, no investigation of applicants. When applicants were investigated by the Charity Organization Society for this clinic, about fifty per cent. were found able to pay or unknown at address given to the receiving clerk. The material for clinical instruction is far in excess of the demand, and still the clinic is being enlarged. It certainly seems as though something ought to be done to prevent these abuses of medical charity. It was only recently a young woman applied at one of the classes, and asked to be attended to at once as she had *left her bike outside*.

Applicants from out of town are not a curiosity at any of the clinics.

The abuse of medical charity seems a fit subject for agitation, and it would be well to hear from others on the subject.

C. F. G.

New York, September 25, 1895.

THE COMMITMENT OF THE INSANE.

To the Editor of the Medical Record.

Sir: In view of the laxity of the laws governing the commitment of the insane, experienced and practical observers must, perforce, endorse some of the views of Mr. Albert Bach on the subject. It is well perhaps to take the ideas of Mr. Bach on some matters "cum grano salis," such, for instance, as the statement in his recent paper on suicide concerning the practice of physicians in promoting euthanasia. Such rhetorical hyperbole causes us to suspect that at times Mr. Bach is given to extravagance of language, if not wilful falsification. However, that the present lunacy law is inadequate, as he claims it to be, is a fact apparent, if we examine for a moment some of its features and the results arising from the necessary observance of it, in its imperfection.

It may be stated that the present law was enacted in 1890, and is an amendment to the revised statutes of 1889. The law of 1889 was in most respects the same as that in force since 1874, except that the certificate, or a duplicate, must be registered with the State Commission in Lunacy. Let us see what the law requires in a medical man before he can qualify as an examiner in lunacy. The first requisite is, that he must have been in the practice of his profession for three years; and the second is, that he must be registered, after approval by a judge of a court of record, with the Lunacy Commission; that is all.

Now, of course, insanity as a rule is not hard of diagnosis, almost any one can do it. The certificate is easy to make out; signing and swearing to its statements are simple matters, and it may seem absurd that we should need a specialist to do something an intelligent layman might do. But this is not all; the average medical man is able to say of the plain case of mania or of melancholia, such and such are the symptoms, and this the diagnosis; more, however, is required of him. The question is not always is the patient insane? but it is, also, is his insanity of the

kind that would be benefited by hospital treatment? Should a patient suffering from simple melancholia, with its terrifying depression, and often its keen realization of surroundings, have the often-time unpleasant sights of a hospital for the insane added to the many subjective miseries incident to his disease? Will a three years' experience in practising medicine, the practice consisting often of "holding down" an office chair, enable a man to pass upon such a question? Again, there are many cases whose symptoms, although an open book to one that has had practical experience in psychiatry, will seem normal and of sound mind to a man that knows more of fractures than of physiological psychology, and is more versed in the varieties of bacilli than in the anatomy of the cerebral convolutions.

It may be well to state here that I do not claim that every examiner in lunacy should be one that has made alienism a life-long study; but he should have a well-grounded theory of mental medicine, and a certain amount of practical experience in its diagnosis and treatment. The chairs of psychiatry in most of our colleges are more ornamental than useful, and the few lectures delivered on the subject are sparsely attended as a rule. So we cannot expect an average examiner in lunacy to know very much on the subject whereof, by reason of his power of certification, he professes to be an expert.

So much, then, for the requirements of the present law in regard to the qualifications of the examining physician, and when it is stated that in New York City alone there are five hundred and two registered examiners in lunacy, it will be seen that many have availed themselves of the simple requirements of the position to pose occasionally as expert alienists and add materially to their income by so doing.

In regard to the other provisions of the law, requiring the approval by a judge of a court of record, the operation in its simplicity and ease of accomplishment make the approval almost farcical. The readiness of our judges to approve of medical certificates of lunacy applies more to the rural districts; there the procedure is done in a hap-hazard way only too frequently, the real committing magistrates being the physicians. Of course, physicians should be like Cæsar's wife; but, unfortunately, the millennium is afar as yet. In New York, lately, certain of our prominent judges have ceased signing certificates in a promiscuous manner, and have shown, by their unwillingness to sign, their disapproval of the law's laxity.

The safeguards against mistakes and false commitment are more numerous than in former years, but that they are far from perfect I think most practical alienists will agree. The remedies are simple and easily applied. Cut down this immense list of insanity experts (?) by making it imperative that an examination, practical and theoretical, in which experience will largely count, must be passed, to determine the competency of the physician. Lengthen the time for the physician required to be in practice. Make it compulsory for the judge to see the lunatic about to be committed before signing any certificate, for no patient is so violent that he may not be seen, at least privately, by the magistrate. By means of these and other precautions our lay friends, with minds as richly imaginative as Mr. Albert Bach, will no longer have cause for alarm.

WHITMORE STEELE, M.D.
155 EAST SEVENTY-SEVENTH STREET.

How to Rescue a Woman.—A French medical journal says that the authorities at Dieppe have issued instructions to the bathing-police, among which is a paragraph directing them never to seize a drowning woman by the hair, as that might come off, leaving the owner to sink.

THE ABUSE OF PUBLIC CHARITIES, AS SEEN FROM A HUMANITARIAN STANDPOINT.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: The present is an age in which pessimism flourishes with a fecundity astonishing to even the greatest of the brotherhood. That the medical profession is remarkably free from this noxious quality goes without saying; yet, now and then, a solitary case will occasionally make its appearance upon the surface, even where the intention is of the best. When such occurs the majority of the profession are inclined to regard the idiosyncrasies of the individual with a regretful eye, that one who is a member of an honorable profession should allow himself to become morbid. And yet it is a misnomer to call him an extremist, for he is a pessimist in the widest sense of the term who permits himself to hold such a misanthropic estimation of his fellow-men as does the author of "The Abuse of Medical Charities," which appeared in the issue of the MEDICAL RECORD of August 31st.

A cursory perusal would lead the reader to believe it to be a most erudite and profound, logical and sound discussion of a matter in which it must be admitted we are alike interested. But a close and critical examination of the article reveals that it is made up of a tissue of generalities and assertions, few of which are substantiated, and a mass of tiresome repetitions. In fact, the writer betrays a lamentable lack of knowledge with regard to worldly affairs and people, and makes a furious onset upon those who appear respectably clad at free dispensaries, claiming that if well dressed the applicant must be able to undertake the expense entailed on treatment by a specialist.

He cites, or rather indulges in, the parable of a wealthy brother bringing his poorer relative to be treated at the free dispensary; of wealthy employers sending female help; of family physicians who, having exhausted their every known remedy in the treatment of some complaint, consign their patient to the tender mercies of a free dispensary.

And now, what is to be understood by a free dispensary? Does it mean a place where one afflicted with disease may be treated without charge, or is it an institution where there is a class distinction and only those clad, or, rather, not clad, in becoming garments may be prescribed for?

Is it any wonder, then, that, dreading the treatment which a number have experienced, many will appear in costumes which at least cause them to be treated with respect and courtesy? Is it to be supposed that only those who are financially well off are sensitive to the gibes of some follower of Æsculapius? Let one interested visit one of these dispensaries where poverty is predominant and listen and witness the scenes there to be found. Why, then, should these institutions advertise free treatment, and when once the patient is within the toils demand a fee? As well might the attending physician make a demand as to the amount of money in the patient's possession and hold him up in the regular fashion of Claude Duval. It would be fully as honorable and far more manly. In other words, it is nobody's business, and is an impertinence which in any other profession or business would be sharply resented. Frankly speaking, a free dispensary is an institution open to all who stand in need of treatment, and if any physician feels that he is being robbed of his just profits in attending patients who may happen to appear in becoming dress, he may easily find a remedy by severing his connections with an institution where such patients are liable to put in an appearance.

It is folly to inveigh against applicants of foreign extraction who appear at the clinics for treatment, and claim that a very large number of them are able to pay. Statistics plainly prove the fallacy of the assertion. True, there are some who could pay, but the number

is infinitesimal in proportion to the number of applicants for relief. The evil may, as the worthy author of "The Abuse of Medical Charities" asserts, be increasing, but I deny most emphatically that it is begetting habits which tend to degrade the undeserving recipients. Such cannot be degraded, as, in a certain sense, they have tasted the very dregs of degradation, inherited, unfortunately, from a long line of ancestors born in serfdom. Is there a remedy? Perhaps, and yet to find and cut off the evil in this direction we would be obliged to check the tide of immigration, and, as does the great wall of China, effectually shut off this invasion of the vandals who, devoid of conscience, rob the poor physician of his just fees at the free dispensaries.

Imagine the able-bodied mechanic, clerk, typewriter, bookkeeper, etc., with the princely salaries of $8, $10, $12 to $18 per week, many with large families dependent upon their daily toil, paying for special treatment! Or take a school-teacher (many of whom receive but $400 per year, and few of whom have visited a dispensary); how long is it to be imagined they could undertake a special treatment? All of these people must appear well dressed at their places of business or discharge would quickly follow. And yet, it is asserted, if these holders of lucrative positions (?) appear at the free dispensaries, treatment should be refused them. Yet the school-teacher dares not appear other than becomingly clothed. How, then, are professional men to judge of the ability of the patient to pay? "Ay, there's the rub." They dare not say, "Pay me at once," for then they assume the character of extortioners, and as they have the attributes of honor and manhood they will have a natural repugnancy thereto.

It is useless to raise the alarm-cry of pauperism, because a large number of people financially embarrassed, and among whom is a small proportion of well-dressed individuals, are obliged to visit the institutions known as free dispensaries. A large number of those treated have a natural pride which forbids their attending these places. But necessity knows no law, and they perforce do that which is obnoxious to their feelings.

The abuse of these public charities, if such exists, has produced no visible impression upon the public mind. On the contrary, with the exception of some disgruntled individuals, the general verdict is one of approval. This is the more marked that, considering the proportion of patients who receive free treatment to our enormous population, the number who abuse the privilege is infinitesimally small. Can as much be said of cities of like population in other parts of the universe? Statistics fail to reveal it.

As to a remedy for the correction of the abuse of charity, I can suggest nothing which could be put into practical operation. As long as free institutions continue to exist, so long will the people continue to fill the reception-rooms of clinics. If the precept and principles of the Good Samaritan are to be thrown aside, then take down the placard, "Free Treatment," and at once advocate the total abolition of free dispensaries. When this is accomplished, and not till then, will the poor physician of the free dispensary receive his just proportion of the fees which should accrue to him, and likewise the execrations of millions of his unhappy fellow-beings.

THOMAS J. MOSS, M.D.

NEW YORK, October 5, 1895.

Troubles of the German Insane Asylums. — There seems to be, says the *Medical Magazine*, a general awakening in the German insane asylums. Following on the exposures at Mariaberg and Anelsburen comes news of trouble at the Bielefeld Institute for the Insane. The doctor in charge accuses the directors of "gross excesses" against the inmates of the asylum.

A BIT OF ANCIENT HISTORY.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: In the *Southern Journal of Medicine and Pharmacy* for September, 1847, Dr. W. T. Wragg states that he has been in the habit of using animal ligatures for upward of ten years, and for several years has used none but these. During this period he has tied arteries of the fingers, arm, forearm, leg, and thigh, and has never seen any symptoms result from which he could infer that the knot had not been removed by absorption.

His deductions are: 1. That the deer-sinew ligature, if properly applied, will effectually arrest hemorrhage from vessels of even large size. 2. That they produce less inflammation of the living tissues with which they are placed in contact during the time they remain within their substance. 3. That they are susceptible of being absorbed and carried away by the action of the living parts in which they are placed.

JOHN A. WYETH, M.D.

NEW YORK.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending October 5, 1895.

	Cases.	Deaths.
Tuberculosis	116	109
Typhoid fever	36	7
Scarlet fever	27	2
Cerebro-spinal meningitis	2	5
Measles	37	5
Diphtheria	142	24

Strychnine Delirium.—Those members of the medical profession who have employed caffeine very largely in the treatment of cardiac and renal disease, have recognized that large doses of this drug, continuously administered for a considerable period, developed in certain individuals what has been popularly called "caffeine craziness." In other words, the full medicinal doses required by the condition of the heart or kidneys have also been sufficiently large not only to produce an increased activity of the brain, such as is seen when coffee is taken in large amounts, but also have gone farther than this, and by the very cerebral stimulation produced temporary insanity. Within the last few years the medical profession has been employing in certain States what may be considered as massive doses of strychnine in the treatment of failing respiration or circulation, and has obtained therefrom very good results. It having been found that these full doses of strychnine acted favorably when given in an emergency, we have been tempted to continue their administration where the symptoms were relieved but temporarily, and, as a result, have oftentimes been pleased with their effect. On the other hand, a sufficient number of cases have been seen in which cerebral disturbance has followed these large doses to put us continually on the lookout for such untoward symptoms. As a rule, he who administers large doses of strychnine in an emergency is on the *qui vive* for some twitching of the muscles of the forearm or other portion of the body as an evidence of the physiological action of the drug. While we believe that these symptoms are commonly produced by a single administration of the remedy, we are also confident that its continued administration in full doses frequently fails to produce these evidences of heightened reflex activity, and in their place causes a more or less active delirium, in which

the patient frequently refuses to take his medicine, or develops the delusion that his attendants are conspiring to poison him or do him some other injury.

Dividing Fees with Midwives.—At the meeting of the Aerztekammer held on the 18th ult., under the presidency of Dr. Achenbach, the new Medzinal Taxe proposed by the Cultus Minister was the chief object discussed. In almost every instance the fees proposed by the Minister were considered as too low, and alterations from this point of view were made as counter-proposals. It is scarcely likely, however, that they will meet with the acceptance they deserve. A second matter discussed was the practice of paying a fee of three shillings for every case of labor introduced by a midwife. This curious practice was not originated by some practitioner in need of practice, but by the University and Charitié kliniks. There was a fear that, as Berlin was a large teaching centre, the number of cases of midwifery would fall short of the requirements for due instruction ; it was agreed, therefore, that a reward of three shillings should be given for every obstetric case introduced. This went on for a number of years. When Professor Martin began his extra-mural teaching as lecturer on obstetrics, he found he was handicapped by the premium thus given in working in rivalry with the official institutions, and it became a necessity for him to offer the usual fee paid by the two official bodies. It was, however, considered improper for a private individual to pursue the same course as the two public bodies, and his action came before the Aerzte Vereinen for discussion, and was referred by them to the Central Committee. It was recognized by this body that Dr. Martin did not pay the objectionable fee for his own direct emolument, but simply in order that his teaching facilities should not suffer by the action of the colleges. They, therefore, declined to interfere. The way was thus paved for others, and very soon individual practitioners agreed with midwives to pay them the fee for introductions to midwifery cases. These, however, were without the necessary excuse that these cases were required for teaching purposes, and it was considered that by their action they infringed the rules that ought to govern the relations of medical men among each other. After some discussion, in which no one attempted to defend the payment of premium for introduction, the Chamber unanimously agreed to request the Staatsregierung to compel thé Royal Obstetric Institution to put a stop to the payment of such fees. The Chamber further declared all business arrangements of medical men with the lower "Heilpersonal" to be improper.—*The Medical Press.*

Charaka-Samhita.—Part XIII. of this interesting and curious work deals with food and drink, showing what purposes are served by the fluid into which food is changed in the stomach and what by the refuse of food. Those bodies which are particularly liable to disease, and those which are capable of resisting disease, are indicated. Then are mentioned the different diseases which arise in different parts of the body, owing to the excitement of wind, bile, and phlegm, individually, or in pairs, or all together. When they all get excited together the condition is serious, and can only be subdued by the treatment indicated. The difference is set forth between men that are wise and those that are foolish or ignorant. The wise observation is also made that things which are beneficial for some are not always so for others. The concluding pages deal principally with the distinction between good and bad physicians. The bad physicians are called killers of life and helpers of disease. These men, wearing the robes of physicians, are the thorns of the world. Behaving after the manner of those whom they imitate, those persons, through the heedlessness of kings, move about in all countries. This is their especial indication, viz.: clad in the robes of physicians and indulging in self-praise, they walk along the public streets, in expectation of calls. The translator adds that to this day many physicians who have no calls pass and repass along the public thoroughfares in their good and handsome carriages drawn by excellent steeds, to create the impression that their practice keeps them engaged for the whole day.

The Craig Epileptic Colony.—Craig Colony, named for the late Oscar Craig, of Rochester, formerly President of the State Board of Charities, consists of nearly one thousand nine hundred acres of land in the Genesee Valley. It is reached by two trunk lines of railways (the Erie and the Delaware & Lackawanna) and from roads centring at Rochester by the Western New York & Pennsylvania Railroad. The colony has its own post-office and railway station, known as Sonyea, an Indian word signifying sunny place. The law establishing the colony required that it should be arranged on the village plan. Craig Colony will not resemble an institution in any particular, but will look more like a country town than anything else. As the patients are received they will be set to work or at study in various ways. They will take care of the farms, gardens, and orchards ; they will plan and build new houses. There will be among them tailors, shoemakers, printers, bookbinders, masons, ironworkers, carpenters, painters, and so on. In fact, every sort of employment, every sort of recreation, everything in short that goes to make up the life of a country village, will be found in this colony, the only difference being that the citizens of this community will be epileptics. The resources of the land are such that almost everything in the way of food for the inhabitants of the village can be raised by themselves, and their surplus agricultural and manufacturing products judiciously managed can make the colony practically self-supporting. Work has been progressing very rapidly during the year to prepare existing buildings for the reception of patients. The first quota of patients, numbering sixty, will be taken from the almshouse early in November. The patients taken from the almshouses and asylums will be known as State patients, and they will be provided for before any private patients can be received. They will be sent to the colony by the poor authorities of each county according to a form required by law, the blanks for which will be furnished on application to the State Board of Charities, or the superintendent of the colony. As soon as all epileptics now upon public charge eligible for admission to the colony are provided for, private patients will be received at prices to be regulated by the Board of Managers, according to the kind and extent of care and attention required. Such patients may, if it be desired, erect cottages for their own use upon the grounds, upon application to the Board of Managers. There will be no restriction as to the age of patients admitted, and the only restriction practically applies to the mental condition. Insane epileptics, or epileptics subject to insane outbreaks, cannot be taken into the colony. The law permits the Board of Managers to take and hold in trust for the State any grant of land, gift, or bequest of money, or any donation to be applied, principal or income, or both, to the maintenance and education of epileptics, and the general uses of the colony. Dr. Frederick Peterson is President of the Board of Managers, and Mr. H. E. Brown, Secretary. The medical superintendent is Dr. William P. Spratling, Craig Colony, Sonyea, N. Y.

An Early Sign of Tabes.—Dr. James J. Putnam, writing in the *Boston Medical and Surgical Journal*, says that a number of years ago, while trying the effect of hyperflexion of the legs for relief of pain in tabes, he observed that it was frequently possible to flex the leg at the hip, without bending it at the knee, so far that it would almost touch the ear without exciting the painful sense of popliteal tension which is so speedily felt by a person in health. Since then he had con-

vinced himself that this sign is not only an interesting feature of advanced cases of the disease, but that it may help one out at an early stage where the diagnosis is doubtful. The degree to which the hyperflexion is possible without exciting pain seems to be proportionate rather to the pain than to any other symptom, and is not proportionate to the ataxia. The sign, Dr. Putnam thinks, is certainly one which deserves study, though it is not invariably present.

The Treatment of Chancroids in Women. — The standard treatment for soft chancres is the application of iodoform, but there are several difficulties to be met with in carrying out this method with females. It is, perhaps, less easy to obtain rest than it is with males, while the disagreeable and penetrating odor of iodoform often causes women to shirk its application. Even if the drug be used as ordered, the lodgement of urine between the labia after micturition and the free vaginal discharge rapidly decompose the chemical and neutralize the good it might do. Von Herff recommends the employment of immediate cauterization by phenol, his method being as follows : Having first well cleansed the genitals with sublimate solution, search is made for the full extent of the disease in a good light. Each ulcer is then touched with a concentrated solution of phenol, a wooden probe being used for the purpose. The edges of each sore must be especially well touched up. Dry wool is then placed over the ulcer, and hip-baths and weak antiseptic injections used afterward. A further examination need not be made for about five days, when the ulcers will, as a rule, be found healing.—*Medical Times and Gazette.*

A Choice of Occupations.—The editor of the *Provincial Medical Journal* says that he attended a meeting of the Section on Ethics of the British Medical Association in company with a successful practitioner who takes only guinea fees. The gentleman listened with attention, but upon leaving the room he said "You have lost your sense of humor. Why, they were actually talking about the dignity of the profession, while in the same breath they discussed the question whether they should attend a man for 3/6, 4/, or 10/ a year." He had never before heard of such a thing, and as his idea of dignity was associated with a guinea fee for each consultation he could not understand it, nor does he yet, says the writer, though we had a long conversation on the subject, and we told him of the conditions of practice among the vast majority of the profession. "Well," he said, "I would break stones first." "It is easy to talk," adds our esteemed contemporary, "about breaking stones for a living, but this form of avocation would not be available, for there are already too many applicants even for that very unremunerative form of making a living."

A Glass Syringe as a Feeding-cup.—Dr. Aulad writes to the *Medical Times and Hospital Gazette* that he was one day attending a child who struggled violently when any vessel or spoon was brought near her mouth. He filled a small glass syringe with milk and held the nozzle over her mouth as she lay in the semi-recumbent position, pushing the piston and allowing the liquid to fall, drop by drop, into her mouth. Very soon she made no objection to allowing the nozzle to be inserted between the lips, and commenced to draw, as from a teat. Dr. Aulad subsequently employed this method with adults only, using a larger syringe, and he says that it is surprising with what ease and comfort patients can thus be induced to take a large amount of liquids—from a few drops to an ounce at a time.

Hereditability of Cancer.—Mr. Roger Williams holds that the fact which he has demonstrated, that cancer is so often homotopic in its transmission, that is to say, that it attacks the corresponding organ in each of the related individuals with preponderating frequency, proves conclusively that the disease may be inherited. The following cases, which he mentions in a letter to the *British Medical Journal*, appear to illustrate this, he thinks, in a particularly striking manner: 1. A woman, aged fifty-three, came under his observation with uterine cancer, whose maternal grandmother, mother (aged forty-five), mother's sister, and the patient's two sisters (aged thirty-two and thirty-six) had all died of cancer of the uterus. 2. In a case recorded by Sibley, a mother and her five daughters all died of cancer of the left breast. 3. Of the celebrated Bonaparte family, Napoleon I., his father, his brother Lucien, and two of his sisters, all died of cancer of the stomach.

The Average British Practitioner is a funny creature, if we may be permitted to generalize from the samples we find revealing themselves in the columns of our London contemporaries. He never seems to know how to act in emergencies not provided for specifically in the decalogue or in "The Manners and Rules of Good Society." Some time ago the question was agitated in the *Times* whether, when a man met his wife's maid or the cook on the street he should raise his hat and smile, or should simply ignore her presence. Now it is a question of raising one's hat to one's rival's wife, and "Perplexed" appeals to the *British Medical Journal* for advice in the following terms: "A is a practitioner in a neighborhood, who, till lately, was unopposed. B comes in and sets up against A. As is customary B calls on A, but does not see A's wife during his call, and yet a few days afterward B meets A's wife in the street and raises his hat to her. A's wife tells her husband, and A calls on B and remonstrates with him, and considers his wife insulted. Was it an insult, or was B merely indiscreet? Allowing that it is a breach of ordinary etiquette to raise one's hat to a lady to whom one has never been introduced, is it not possible that B, in his anxiety to be courteous to A, overstepped the bounds of propriety?"

The answer of our esteemed contemporary is tender and judicial, but not, in our opinion, satisfactory, for it leaves the question undecided, and "Perplexed" is no better off than before. "Although," so the decision runs, "in the absence of a personal introduction B would have been more than justified by the rules of social etiquette in passing A's wife unnoticed, and, probably, under the peculiar circumstances, would have acted more prudently by so doing, still, the simple raising of his hat would not, as alleged by her husband, constitute an insult, but should rather be looked upon as a natural and courteously intended act toward the wife of a brother practitioner to whom, in accordance with the medico-ethical rules, he had recently paid the customary visit of courtesy as a newcomer; and, in our opinion, A would have acted wisely in accepting it as such. Probably, however, and not unnaturally, his mind and temper were somewhat disturbed by the prospect of professional competition in his hitherto unopposed practice."

The next time B sees Mrs. A coming in the distance he should quicken his pace, take off his hat, and mop his brow as though suffering from heat and humidity. He will thus avoid the insult of passing the lady with covered head, and will not commit the discourtesy of raising his hat to an unknown lady; he will also appear to be busy, and that will make the other children feel real bad.

An Austrian View of American Medicine.—The *Wiener Medizinische Blätter* says that of the one hundred and forty medical schools in the United States only fourteen require a four years' course in order to obtain the degree of Doctor of Medicine. One hundred give a diploma on the completion of three courses of lectures, and twenty-five schools require but two courses of lectures. The length of these lecture-courses varies from five to nine months. The same

journal asserts that the practice of the healing art in the United States is entirely unrestricted.

The Alleged Achievements of the Orificial Surgeon, as set forth in an orificial exchange, are little short of the marvellous, and force the conclusion that the fool-killer has abandoned his occupation. We read of a late case of "phthisis cured by the operation for laceration of the cervix." A case of chronic eczema of the hands was "cured by stretching the rectum." Another case of eczema was treated by "clipping irritated points at the various outlets of the body." This seems vague but heroic. And so on. For all the ills that afflict the flesh, the blame is laid at the door of one, or some, of the orifices of the body, from the puncta lachrymalis to the meatus urinarius, and this, or they, must needs be opened and stretched by the most approved orificial methods. A worse species of quackery was never invented. One orificial gentleman thinks that a "conservative orificial surgeon should be connected with each of our State hospitals for the insane." An exchange says this idea is an excellent one, if he be connected in the proper capacity—as patient rather than as surgeon.—*Atlanta Medical and Surgical Journal.*

Sanitary Science.—At a test-examination for sanitary inspectors, one of the candidates, when asked what a death-rate was, replied that it was a rate levied on the living to support the cemeteries. There is a weird sarcasm in this answer, and also in the reply to the question about the wilful exposure of a person suffering from an infectious disease. "He must not," said the examinee, "ride in any conveyance except a hearse without first informing the driver." Another reply to the same question laid it down as imperative that "a person dying of an infectious disease must give notice to the local authority within twenty-four hours." A candidate who evidently thought drastic measures should be employed in cases of infectious disease, said that "members of a family where small-pox has broken out must be sent to a hospital and well boiled." Another mildly remarked that "among the precautions against small-pox vaccination might be looked for." In answer to some physiological questions, one examinee asserted that nitrogeneous foods built up the "waist" of the body, and that "milk is the best food for children because it does not require any chewing." Another candidate gave the following elaborate and curious reply to some questions with regard to clothing: "In hot countries the perspiration which is in the skin is evaporated into steam, which goes up to form clouds, and comes down in the form of rain." Sometimes the answers are most illogically "mixed," as in the case of one which stated "that it would be necessary to get an order from the Sheriff to seize and destroy the Medical Officer of Health," and in another which affirmed that "many articles of food have to be adulterated to keep them pure."—*Bristol Medico-Chirurgical Journal.*

The Pathology of Thomsen's Disease.—It is barely twenty years since there was described in the *Archiv für Psychiatrie* an affection characterized by singular muscular phenomena in several members of one family. The affection, since known by the name of the physician who then first described it, has been studied by many observers, among whom may be especially mentioned Professor Erb, who termed the condition "myotonia congenita." The main features of the affection, apart from its hereditary character, consist in an increased volume of muscular masses, suggestive of a kinship to pseudo hypertrophic paralysis, accompanied by notable impairment of power, and the assumption of a state of tonic spasm on the contraction of the affected muscles. There is, further, an increased excitability to faradism and galvanism, with a tendency to the reaction of degeneration. Moreover, Professor Erb found that ensuing on the "closure contraction" of galvanism there occurred a series of slow and regular undulatory contractions, which gradually spread from the negative to the positive pole, a phenomenon which he termed the "myotonic reaction." Hitherto no opportunity has occurred for full observation of the morbid anatomy of Thomsen's disease, but a paper in the *Revue de Médécine* for March by Dr. Déjérine and Dr. Sottas supplies this deficiency. It is founded upon the case of a man who first came under observation at the age of thirty-two, having since infancy suffered from this affection. It was characterized in him by marked hypertrophy of the muscles of the lower limbs and trunk, and less obvious change in those of the upper limbs. All the muscles of the body were rigid when in contraction, and were but slowly relaxed; the myotonic reaction was present. The patient succumbed at the age of thirty-seven, from acute nephritis. No change was found in the nervous system, central or peripheral, but an examination of the muscular system, specimens being taken from all parts, afforded an insight into the nature and progress of the lesions therein. These lesions consisted, in the first place, in a nuclear overgrowth, following which the muscular substance proper apparently becomes swollen, the fibrillæ becoming fused together, while the transverse striation is retained or is even more pronounced than normal. Measurement showed a notable increase in the diameter of the affected fibres. There is, further, a like increase in the interfibrillar protoplasm, rendering the "Cohnheim's fields" more distinct. In more advanced stages the muscular substance disintegrates, and vacuolar spaces are formed in and between the fibres. It is remarkable that the connective tissue does not undergo any hyperplasia, nor is there any excess of adipose tissue as in pseudo-hypertrophic paralysis. It may be remarked that the changes described in this paper agree in the main with those found by others who have examined fragments of the hypertrophied muscles excised during life; but the record of Dr. Déjérine and Dr. Sottas is far more complete, since they had the opportunity of tracing the changes from early to advanced stages. It is pointed out that the hypertrophy commences and is most marked in those muscles which are the most exercised, and it is concluded that in Thomsen's disease we have to do with a "hypertrophy of functional origin." The affection thus ranks with the group of dystrophies of the muscular system known as primary myopathies.—*The Lancet.*

Suicide and Crime in Russia.—Professor Sikobski, of the University of Kief, writing upon the psychology of the Russian people, brings forward some interesting statistics concerning the frequency of suicide in the different nations of Europe. (*The Lancet.*) According to these figures, the death-rate from suicide per million living, is in Saxony, 311; in France, 210; in Prussia, 133; in Austria, 130; in Bavaria, 90; in England, 66; while in Russia it is as low as 30. Further, it is found that during the last thirty years the suicide-rate has in Russia remained stationary, while in all other European countries it has increased by thirty or forty per cent. The exact significance of figures such as these, relating to so complex a phenomenon as suicide, is not easily brought out. Few, however, will be disposed to question the assertion that much of the explanation of the low rate in Russia is to be found in the patience and long-suffering of the Russian peasant under even the worst misfortunes. Among other characteristics, Professor Sikobski also finds a certain indecision of character which fears to say a word or do an action which shall not admit of retreat or withdrawal. Crime is comparatively rare in Russia; thus, the number of persons tried for murder per million living in the year 1887, was in Italy, 90; in Spain, 55; in Austria, 22; in France, 15; in Russia, 10; in Germany, 9; and in England, only 6.

THE TREATMENT OF FEVERS WITHOUT FOOD, ANTIPYRETICS OR ALCOHOL — WITH RECORDS OF VARIOUS CASES.

BY A. MONAE LESSER, M.D.,

NEW YORK.

SURGEON FOR ABDOMINAL DISEASES TO THE RED CROSS HOSPITAL; MEMBER OF THE ACADEMY OF MEDICINE, ETC.

IN 1886 I began to treat all fevers, medical and surgical, without food, antipyretics, or alcohol. Instead I used large quantities of water and a few simple remedies which I shall describe in detail later on. *Ab initio*, my results were far better than they had been when I still adhered to the older and yet recognized plan of feeding and stimulation.

There is scarcely anything new in my method, which, in a primitive way, was practised by the ancients. Thus I do not come as the herald of an entirely new and startling discovery. Researches into the physiology and pathology of the subject have taught me that in all forms of fever, medical or surgical, the exanthematous, typhoid, or the traumato-septic varieties, we invariably find changes in the gastro-intestinal mucous membranes. In some instances these changes are anatomical, while in the acute and more simple varieties they are chemico-mechanical in character; yet in both the physiological function of the membranes is changed and impaired.

It may not be out of place in this connection, before touching the question of treatment, to refer briefly to the observations of distinguished physiologists who have enlightened us on this point. Beginning with the saliva, Uffelmann[1] says: "The secretion of the saliva becomes diminished by fever, and in high temperature no saliva is secreted at all. In the lower ranges of temperature—he evidently refers to acute conditions—the saliva—normally alkaline—becomes turbid, thick, and sour, and with the increase of the fever the power of the saliva to convert starch into diastase is materially diminished."

Passing over the function of the muscular action of the stomach in digestion, Beaumont[2] records, as the result of his experiments, that in cases of fever the gastric juice is only sparsely secreted, and the mucous membrane is soft and irritable.

Hoppe-Seyler[3] examined the gastric juice of a patient with typhoid fever and found no free hydrochloric acid. This was also the case in other instances where the gastric juice was taken from subjects in whom there was an elevation of temperature. He found it utterly inadequate to carry on digestion artificially even after the addition of hydrochloric acid. The same author expresses the opinion that under these conditions the gastric juice has a tendency to become neutral in reaction, and stomach digestion can no longer go on. Instead, we get lactic- and butyric-acid fermentation and the formation of gases, and with them we find the sarcinæ ventriculæ and other micro-organisms, first observed and described by Goodsir[1] and Manassein,[2] who also proved that the observations of Hoppe-Seyler were correct.

Gluzinski, of Cracow, records that he found neither hydrochloric acid nor peptones in the gastric juice during the entire stages of typhoid fever.

Explaining the cause of dyspepsia in fever, Landois[3] says: "The secretion of a peptone forming fluid is arrested when the fever begins very violently, when there is great weakness, or when high temperature long continues." This author also emphasizes the fact that the gastric juice is diminished in all cases of fever.

It is well known that in acute febrile conditions, notwithstanding that the bile is diminished in quantity, it is more watery and poorer in specific ingredients. That similar changes occur in the pancreatic and intestinal juices is shown by Stölnikow,[4] who says: "In high ranges of temperature the pancreatic juice is diminished. Examination shows fat in the form of drops and bundles of crystals which may be isolated from the stools." He also found that fluids are quickly absorbed in persons with elevated temperature, whereas the absorption of peptones is much diminished. This is also established by Beaumont and others.

In the face of these facts it became a question to me whether it was justifiable to introduce into the animal economy food that cannot be disposed of and utilized, and that can at best only act as a foreign body, undergo putrefaction, and give rise to ptomaines, that in themselves must tend to elevate temperature.

My experiments and observations at the bedside have in every way borne out my reasoning. At the meeting of the Academy of Medicine, last March, in discussing a paper on the treatment of typhoid fever,[5] I said: "I have in times gone by employed the milk diet in typhoid fever. One patient refused it and I gave her only water, and she was able to live upon it for twenty-one days.

"From that time on I began to investigate how much or how little food my typhoid-fever cases needed. While I do not yet presume to generally recommend the method so new, still what little I have to say upon the subject of allowing typhoid-fever patients no nourishment whatever, save water, is based upon my results in eight cases, all of which made a good recovery without relapses, and in which from five to fourteen days I permitted the patients to take nothing but water *ad libitum*, only administering diluted milk at the expiration of that time, or rather when the patient expressed a desire for some nourishment. In these cases I had no occasion to use alcohol or antipyretics, although the range of temperature was such that according to the recognized methods of treating typhoid fever I would have been justified in administering them. I have since adopted this plan in all fevers in which the temperature is over 102° F."

My method of procedure is as follows: First of all the bowels are flushed well with a high enema of lukewarm saline water. If the tongue of the patient is pale, covered with a white or grayish coating, I prescribe two hourly doses of a teaspoonful of a solution of sodium

sulphite, 4.00 to 60.00 of water while, if the tongue has a red base, clean, or is covered with a dark brown or grayish coating, I administer dil. muriatic acid 1.00 to 100.00 water in the same doses at the same intervals.

Should the stomach be in a highly irritable condition, nothing has given me greater satisfaction than a two-hourly teaspoonful dose of a mixture of carbolic acid, 1.00 suspended in a solution made of 30.00 of mucilage to 125.00 of peppermint-water. If the disease be a painful one or involve serous membranes, doses of 0.6 sodium salicylate in 100.00 of water are repeated every two hours until all pain has subsided; I have found this remedy to be most serviceable and far preferable to the opiates.

There are occasions in which the stomach may be found to contain a large quantity of food. In such instances I freely lavage, or if the case is suitable, begin with an emetic before administering any other drug. I have seen cases watched by careful nurses where large quantities of undigested milk coagula were returned in the lavage. I recall a case in which washing revealed an unusually large quantity of milk coagula taken nineteen hours before, and another which returned a partly putrified oyster which the patient had swallowed whole twenty-three hours previous.

It is from experiences like these that I have made it an absolute rule to empty the stomach in cases where I suspect the presence of food. The results which have followed this apparently heroic commencement of treatment were such that I did not find it necessary to continue medication in large doses for any length of time. The pulse improves and very soon the patient begins to be more comfortable, the headache, malaise, and other annoying symptoms gradually diminishing in severity.

Be it understood, however, that I do not claim to lessen the duration of any disease of certain course.

I also have the patient sponged frequently with water three degrees lower than the prevailing temperature. If this be above 104° F., under no circumstances do I permit any nourishment to be taken. However, when the pyrexia is lower than this, and the patient craves for something, I give clear broths, containing, as I believe, the salts of the meat only; rice and barley-water with a pinch of salt, but never do I attempt to induce the patient to partake of food. Simultaneous with the lowering of the temperature I have observed that the patients become desirous for nourishment, while on the other hand their aversion to it increases as the temperature rises.

I now continue with whatever medication is indicated. I have altogether discarded the internal administration of antipyretics, as I think they diminish the tone of the heart, thereby deluding us into the belief that our patient has improved simply because the temperature is so many degrees lower, when in reality his vital powers are much weakened and he has less resistance to combat his disease. This fact Cantani [1] has so beautifully made clear to us. The bacillus also can thrive and propagate much better in lower than in higher temperature.

As to medication, I employ aconite in 0.6 to 250.00 of water, of which I give teaspoonful doses every hour, not to diminish the temperature or lessen the frequency of the pulse, for aconite in these doses, in my opinion, acts as a heart tonic, in that it relieves the pressure upon the capillaries and so equalizes the circulation.

I administer aconite at the onset of the disease if the pulse is frequent and weak, the extremities cold, while I prefer veratrum viride in the same doses and same intervals as the aconite, when the pulse is rapid and full.

It is astonishing to see how rapidly the small doses of these two drugs act. I have not yet had occasion to have recourse to alcohol in any of my cases. If heart tonics are needed, I rely upon caffein, providing the heart-sounds are weak, and upon nitro-glycerin when its beats are rapid or intermittent.

The dose of caffein I employ repeated as required is 0.15, and of nitro-glycerin 0.0003 every three, four, or five hours, as the case may require. Strychnine in 0.0005 doses I give in addition to either of these drugs, principally when I use nitro-glycerin, always, however, giving these drugs uncombined, and most frequently hypodermatically.

In all these cases water with a trace of sodium chloride, not sufficient to affect its taste, is given *ad libitum*. The quantity taken in twelve hours varies from 1,000.00 to 1,300.00. It is remarkable to observe how readily it is retained by the most sensitive stomach, provided that the organ is free from other food. It is readily absorbed, restoring to the blood the fluids which the intense febrile condition robs from it, and thereby keeping the cells in the different tissues in a mild but constant state of activity; it increases the action of the liver as also the action of the kidneys, lessening their work by secreting bile and urine of lower specific gravity, and holding the specific elements in higher solution.

Of its effect on the intestinal tract it may be said that the juices, although changed in character, become less irritating in their local action, when thus highly diluted, and excessive diarrhœa therefore does not become a complication of the disease—on the contrary, I have found it has a tendency to enhance easy stools from the very beginning.

Thus, in every instance I flush the bowels daily, and have often observed that its returns contained quantities of undigested matter, including coagulated milk, encased in intestinal secretions, even eighteen days after the patient had partaken of any food.

This method of treatment has given me abundant proof of its efficacy, and it is reasonable to assume that when nothing offensive is carried through the digestive tract, nothing deleterious can be carried into the blood and nothing additional brought into the system to support the micro-organism of the disease; while at the same time a constant washing of every portion of the less affected parts of the body is continually going on, until the hungry state of the tissues requires nourishment, as is evidenced by the patient's demand for food.

That this will ease and lessen the danger of febrile disease more than the feeding or stuffing methods, I beg to illustrate in a case of croup, treated in February of last year, and which was seen in daily consultation by Dr. O'Dwyer.

When first I suggested the advisability of administering no food, save water, Dr. O'Dwyer dissented, and for two days we gave milk at regular intervals. We observed that within half an hour after the administration of the milk, the patient was seized with paroxysms that were associated with a rise of temperature and general indisposition. After forty-eight hours of this state of affairs, Dr. O'Dwyer agreed to continue the treatment without nourishment, on water alone. We pursued this course for three days, during which time the temperature gradually dropped, and the paroxysms became less frequent and the patient's general condition materially improved, until at the end of the third day the temperature had fallen to 100° F., and the favorable outcome of the case was assured. We then resorted to mild feeding with well-diluted milk, and in one week our case was fully recovered without any sequelæ. The usual remedies, including fumigation, were used, but intubation was not resorted to.

Knowing, as we do, that it requires a certain time to digest milk, even with normal secretions, and considering, as Bouchard [1] has shown, that milk increases the temperature when administered in any febrile state, and especially in view of the fact that

[1] Transactions of the International Medical Congress, Berlin, 1890, vol. i.

Auto-intoxication in Disease, p. 217. Philadelphia, 1894.

peptones cannot be absorbed under such conditions, does it not speak loudly against the giving of nourishment as is so frequently practised, with digestive secretions abnormal, deficient, or altogether absent?

I have observed that, contrary to what we might expect, patients kept on water alone lose less weight than those fed upon a mild and easily digested diet, which leads me to believe that water maintains the patient's vitality better than food—that is a food in the truest sense of the term.

It is almost obvious that where the intestinal glands are affected, and the stomach secretions changed on account of an elevated temperature, and with blood containing excrementitious matter, we cannot hope for the utilization of anything that has been taken in for absorption.

Since first I made known my views upon this manner of treating fevers, I find that others have also made clinical observations in line with mine. Among the papers recently published, that will repay perusal, are those of Dr. Licorish,[1] Dr. Page of Boston,[2] and Dr. A. P. Henry.[3]

In the appended reports of the several cases, I have detailed the record and progress of their issue as far as it concerns us most.

I trust that the method of treating fevers as I have described it above from careful notes from my case-book, will prove worthy of further investigation, and I hope my colleagues, especially those who are fortunate enough to possess hospital facilities, will give it honest consideration, and report their results at an early day.

72 East Sixty-first Street.

* The lower temperature and pulse rate marked occurred after food had been withheld a few days.

THE CAUSES AND PREVENTION OF PUERPERAL SEPSIS (FEVER).[1]

By WM. E. GROUND, M.D.,

Superior, Wis.

After so many centuries of vain speculation regarding this dread disease, which surrounded childbearing with such gloom and apprehension, truth and science are at last prevailing. Volumes have been written about the nature of puerperal fever. All sorts of causes have been adduced to explain the protean manifestations of the morbid conditions. A few great minds have occasionally grasped in the direction of the true etiological factors. Even Hippocrates and Galen referred to the fact that erysipelas will affect the womb of the parturient woman, and cause a fatal inflammation; but as often ignorance and superstition ignore and cry down these great truths. Man has ever sought the source of disease in mysterious and remote causes, and has ascribed them to the decree of a blind fatality, or to the caprices of whimsical and fantastic beings. When man comprehends the nature of the elements which surround him, and also his own nature, he will then know the true causes of his evils, and the remedies he should apply.

The true infectious nature of puerperal fever, so-called, has within the last century so gradually dawned upon the minds of physicians, that instead of being considered next to suicidal for a woman to enter a maternity for confinement, a well-regulated maternity hospital is now considered one of the safest places in which a woman can be confined. At the Preston Retreat, in Philadelphia, there were more than twelve hundred deliveries without a death.

In 1843 Oliver Wendell Holmes said: Puerperal fever is so far contagious as to be frequently carried from patient to patient by physicians and nurses. Two or three years later, Semmelweiss attributed childbed fever to decomposing animal matter conveyed to the mother from without. Pasteur, in 1880, was the first to cultivate the streptococcus from the organs of women dead of puerperal fever. Similar observations were subsequently made by Fränkel, Winkle, Doderlein, Winter, Widal, and others, so that now there can be no doubt that the streptococcus pyogenes stands in a direct causal relation to most of the severe and fatal cases of puerperal sepsis. Widal found the streptococcus in a great variety of puerperal affections, including puerperal ulcers, endometritis, parametritis, peritonitis, septicæmia, pyemia, and phlegmasia alba dolens. Many other germs bear an important etiological relation to puerperal affections. Briger, and later Fehling, Doderlein, and others, pointed out the fact that a fatal puerperal fever might be caused by the staphylococcus, but, as a rule, this germ does not produce the severer forms of puerperal sepsis.

[1] Read before the Wisconsin State Medical Society at the forty-ninth annual meeting, held in Superior, June 19 to 21, 1895.

[1] Medical Record, June 2, 1894, p. 706.
[2] Ibid., February 24, 1894, p. 230.
[3] Ibid., May 25, 1895, p. 646.

However, streptococci and staphylococci are frequently found existing together in these affections. Kronig, who is Doderlein's assistant at Leipsic, has obtained a pure culture of the gonococcus from the interior of the uterus in nine cases in which there was a slight febrile disturbance after labor. None of the cases were serious. Energetic research during the last few years has demonstrated that the diplococcus pneumoniæ, the bacterium coli communis, the micrococcus tetragonus, and the bacillus pyogenes fetidus, possess pyogenic powers.

Puerperal sepsis (or surgical sepsis occurring in the parturient woman) is an infectious disease due to germ inoculation of the wounds resulting from the separation of the decidua and the placenta, and from the passage of the child through the genital canal, in the act of parturition.

The next point to consider, then, is what affords these germs an opportunity to inoculate the bruised and abraded parturient canal? This brings us to one of the most important phases of our discussion; viz., do micro-organisms exist normally in the uterus and vagina of pregnant women, or are they placed there by outside influences? Without referring to earlier investigators, I will proceed at once to the consideration of the work of Doderlein. He examined the vaginal secretions of one hundred and ninety-five pregnant women, and distinguished two sorts of secretions, one normal and another pathological. The normal secretion was found in 55.5 per cent. of all cases. It is a whitish, friable substance of the consistence of coagulated milk. The author thinks it is derived from the superficial layers of vaginal mucous membrane, the cells of which, when cast off and mixed with lymphatic fluid, form a white mass. The reaction of the normal vaginal secretion is intensely acid. The acid is lactic acid, and is derived from the tissue changes produced by a definite species of bacillus which is always present in normal secretions, and is called by him "vaginal bacillus." Besides this species of bacillus, Doderlein found in the normal secretion, in a large number of cases, a scizomycete or yeast germ, which he recognized as the germ of thrush, and which, as is known, grows in acid media. He found other micro-organisms, both saprophytic and pathogenic, in normal secretions, but only quite rarely, and he is of the opinion that the vaginal bacilli, inasmuch as they produce acid, render the vagina unfitted for the growth of other germs, and thereby protect it from infection. The author was able to support it by experiment. He introduced the staphylococcus pyogenes aureus into the vagina of a virgin in which the vaginal bacilli were present, and as early as the fourth day they had perished. The pathological secretion differs from the normal by being very fluid and yellowish-white, and containing pus corpuscles. Its reaction is only faintly acid, or neutral, or it may even be alkaline. In the pathological secretion the vaginal bacilli are supplanted by various other saprophytic and pyogenic micro-organisms. The author assumes that the pathological secretion is caused by an increased influx of alkaline tissue fluids, such as is occasioned by excess in venere, by pessaries, by frequent digital examinations, and by gonorrhœal cervical catarrh. Williams, of Johns Hopkins University, has practically substantiated the results of Doderlein. Kronig examined the vaginal secretion of about five hundred pregnant women, and found them to possess reactions of varying degrees of acidity. He found the bacterial flora usually found in the healthy vagina. In no case did he find pathogenic cocci. Kronig and Menge introduced streptococcus pyogenes and pyogenic staphylococci in large numbers into the vagina of pregnant and non-pregnant women, and found they disappeared in a short time. Their observations differ from those of Doderlein only in respect to the rapidity with which foreign organisms disappeared in the normal and pathological secretions. Irrigation of the vagina with water or with antiseptic solution diminished the rapidity with which bacteria in the vagina disappeared. Bacteria introduced into the cervix uteri likewise disappeared in a very short time.

Recently Walthard made some observations regarding the presence or absence of pathogenic micro-organisms in the genital canal of pregnant women, in the Obstetric Clinic of Bern. He found the secretions from the cervical canal to be directly antagonistic to the growth of germs, and that the vaginal secretions possessed antiseptic properties. The author regarded the cervical canal as the border-line between those portions of the genital tract that contain bacteria and those that contain none. An examination of the mucus found in the vagina occasionally revealed the presence of streptococci, with, however, a much less degree of virulence than the same germs possessed when derived from tissues in phlegmonous inflammation, or from the lochia in puerperal septicæmia. The virulence of streptococci found in the vagina is the same as that of the same germs found upon healthy mucous membrane in other portions of the body. They are, in fact, not virulent, but are saprophytic germs upon healthy tissue. They can, however, take upon themselves a malignant character when the resistance of the tissue is diminished, and become the infective germs of puerperal sepsis. In addition to vaginal streptococci, the staphylococci, gonococci, and the bacterium coli commune, produce puerperal sepsis. The bacterium coli commune is occasionally found in the amniotic fluid. The presence of these germs may turn the lochial discharge brownish and offensive, but this condition of the discharge does not necessarily point to sepsis. Highly virulent streptococci and staphylococci may be present on the exposed parts of the healthy body without doing harm, owing to the defences which have been set up against their invasion, and to the local and general resistance offered to their growth. These barriers may, however, be overthrown, and under these circumstances pathogenic bacteria, originally present on exposed surfaces of the body, may cause various local and general diseases. These are the conditions to which the absurd and meaningless term auto-infection is sometimes applied. The term auto-infection has no place in a scientific discussion.

Summing up the results of the investigations of numerous and reliable observers, we may justly conclude that the normal vagina does not often contain pathogenic bacteria. With the exception of the gonococcus, such bacteria do not long survive the vaginal secretions. The practical deductions are that vaginal injections before labor are not only not necessary, but may actually favor septic infection in cases where antiseptic precautions are not carried out strictly. In rare cases with aggravate pathological secretions it may be necessary to flush the vagina with hot sterilized water daily before confinement.

In view of this there can be no disputing the fact that septic infection in the puerperal state occurs almost always from an imperfect aseptic technique on the part of the accoucheur or his assistants in the preparation of themselves or the patient for the lying-in ordeal. The term auto-infection is, strictly speaking, not a fact, and the condition, therefore, a myth. The occurrence of puerperal sepsis is *prima facie* evidence that pathogenic germs have at some time gained admission to the maternal parts from without. That they are always placed there by the surgeon or his assistants is not an established fact. Prioleau[1] insists that there are certainly inevitable forms of puerperal infection which defy rigorous antisepsis during labor and the puerperium. Infection is observed when the labor occurs in an infected or mephitic environment, when labor coincides with the development of an infectious disease, or when the patient has old lesions in or near the genital

[1] Arch. de Tocol. et de Gynec., January, 1894.

tract. The mechanism of this kind of infection is explained. Air charged with noxious principles enters the genital tract. The infected blood of the patient may bring germs to the placental wound in the uterus. Phagocytosis is weak when the blood is already infected, hence the germs develop rapidly in the wound. The primary infection is thus stimulated ; an old genital lesion, abscess, etc., may be awakened, or an old wound or lesion outside the vulva may set up infection in the uterine wound, just as a blood lesion does when pre-existing. Dumont describes a type of puerperal infection from intestinal origin. The cause is alteration of the intestinal mucous membrane from pressure of the gravid uterus, and accumulation of fæces causing stasis and infiltration of the intestinal walls. The alteration consists in desquamation of intestinal mucous membrane, thereby favoring the advent of germs by removing nature's barrier. This alteration permits the bacillus coli communis to pass through the walls into the peritoneal cavity. The colon bacillus is a constant inhabitant of the intestinal canal, but where intestinal lesions exist they frequently invade the internal organs, causing all degrees of septic conditions.

Puerperal sepsis contains the same germs that any other septicæmia contains ; the same micro-organisms which cause suppuration elsewhere. Surgeons formerly regarded a febrile reaction as a necessary accompaniment of the normal processes of repair after all surgical procedures ; now they usually regard it as an avoidable blunder. Still we do have a post-operative aseptic fever, that occurs independent of pathogenic germs. This fever is characterized by the absence of inflammatory symptoms and with little constitutional disturbances. In a large wound healing by first intention, we find not only extravasated blood and exuded serum, but minute fragments of tissue which have been separated from the surface of the wound during the operation, and are subsequently disintegrated and absorbed. These materials when absorbed exert a pyrogenic action upon the system. The exact nature of this pyrogenous substance is not clearly known, but the results of experiments seem to prove its existence in the fibrin generators and fibrinferment of the blood. At any rate their close relationship to living substances renders them but slightly injurious, and they produce in consequence only a mild type of fever.

The most common seat of infection is probably in the uterus itself. The sinuses at the placental site are occupied by large clots, which readily become infected, and from this location the putrefactive and septic elements are readily absorbed, owing to the highly active lymphatic circulation. The lacerated vessels of the cervical canal are also plugged with similar though smaller clots. The cervical absorbents are not so highly developed, hence septic absorption cannot be so active at this point as at the fundus uteri. The comparatively lessened lymphatic circulation of the vulva and vagina render erosions and contusions of these parts less likely to communicate infecting material to the general circulation.

The character and gravity of a septic infection will depend, not only upon the nature and virulence of the infecting germ, but too upon local predisposing causes and constitutional conditions which diminish the resisting power of the tissues, such as nephritis, valvular heart disease without compensation, syphilis, diabetes, intercurrent infections, and anæmia.

Briefly, we distinguish three principal types of infection : First, putrid intoxication or poisoning by toxines secreted by germs growing upon putrefactive foci, before these germs have themselves found their way into the blood. The process is due to the putrefaction of retained clots or placental or decidual fragments in the uterus. The poison may gain admission to the general circulation through the uterine sinuses or the denuded placental site, or through abrasions in the vaginal mucous membrane. This condition is the so-called sapremia of most authors, and is intended to be limited to the products of saprophytic germs, but I do not think we are justified in excluding the chemical products of pathogenic germs. The symptoms depend entirely upon the dose of the poison. The onset of the fever is generally within twenty-four hours. The preliminary chill is usually wanting, but there is a rapid rise of temperature to 101° or 103° F. The prompt removal of the putrefying material from the uterus is soon followed by a rapid fall of temperature, and a disappearance of all alarming symptoms. Sapremia follows most frequently manual expression of the placenta, prolonged and forceps deliveries, version, and extraction.

The second type of infection is bacterial invasion and ptomaine poisoning. The form of bacteria is not always the same, and any of the pyogenic germs may produce septicæmia. The most fatal type is that caused by the streptococcus. The next in order of virulence are the bacterium coli commune, the staphylococci, and the gonococci. These germs invade the uterine sinuses and the lymphatics surrounding them, and from here they penetrate the uterine parenchyma, to the larger lymphatics underlying the peritoneal covering of the uterus. The endometrium contains multitudes of bacteria swarming in its outer layers, while just underneath this layer we find an abundant round-celled formation of granulation tissue, which is the rampart thrown out by nature to prevent the further penetration of invading micro-organisms. In septicæmia the absorption is more gradual, and is aggravated by the more rapid development of the germs. This septic process may extend by continuity of tissue through the uterus to the tube and ovaries, setting up all forms of inflammation in them, and finally involving the pelvic peritoneum ; or the septic infection may extend by the lymphatics through the uterine parenchyma to the pelvic cellular tissue, and ultimately causing a true pelvic abscess.

The third type of septic infection, pyæmia, is merely an advanced or aggravated stage of septicæmia, characterized by abscess formation, the localization of the septic material causing thrombi embolism, and subsequently multiple abscesses in the viscera and joints.

The sources of infection are, first, the midwife or nurse ; second, the surgeon ; third, the husband, or patient herself ; fourth, the air.

Of all the sources of infection, I consider the midwife or nurse the most fruitful. Most of the puerperal cases I have seen have been attended by midwives. They use no antiseptic precautions whatever, making frequent vaginal examinations with filthy, unwashed hands. Untrained nurses are often in attendance at our confinement cases, and not infrequently make internal examinations of the woman about to be confined. Some do this to show that they know as much as the doctor ; others, again, do it to ascertain the degree of dilatation, to aid them in determining when to send for the doctor. When engaged to attend a woman we should instruct her not to permit any attempt at examination by the nurse or midwife, otherwise we cannot always prevent infection from this source.

That the attending surgeon is ever the cause of infection is greatly to be regretted. Happily this is not as often the case now as formerly, but still it does exist. A physician of this age, who attends a case of confinement with less preparation and care than he would bestow upon a capital operation, should be held culpable in case complications of a septic nature should arise. When called upon to attend a case of confinement, proceed at once upon true surgical principles. If time permits, have the patient take a full hot bath. Empty the rectum and bladder, the former by enema. The robe of the patient and the bedding should be absolutely clean. The surgeon should then render his arms and hands aseptic, paying special attention to the subungual spaces. Ethereal soap and hot water should be used freely with a stiff clean brush. Here it may be necessary to remind you of the danger lurking in

questionable soaps and dirty nail-brushes. Nail-brushes should be kept clean and in an antiseptic solution when not in use. I have used ethereal soap with great satisfaction. The external genitals of the mother should be treated much in the same manner. After the scrubbing process has been gone through with, the surgeon's hands and the maternal parts should be rinsed in a solution of creolin. Aseptic towels should be pinned around the thighs and over the mons. The patient is now ready for an internal examination, which should be repeated as seldom as possible. It is a good practice to disinfect the hands each time the maternal parts are touched, and to keep the towel wrung from a creolin solution against the external genitals constantly. Should any accident occur to infect the field of operation, disinfect as from the first, always keeping in mind surgical cleanliness. After delivery the nurse should be instructed not to touch the mother, either to change dressing or to draw the urine, without first scrubbing the hands and nails thoroughly.

Gum catheters had better be discarded altogether, for they are never clean. Use only glass catheters, they can be easily sterilized. The field around the meatus should be carefully cleansed before the catheter is used, and everything clearly in view. After delivery of the placenta an aseptic gauze pad should be worn next the external genitals, and frequently changed.

The husband and the patient are often the sources of contagion. The husband, as a factor in the production of puerperal sepsis, has not, I believe, received the consideration he deserves. He often initiates the septic process in his wife soon after marriage, by inoculating her with the gonococcus, and when she is near the end of pregnancy he comes home with a soft chancre, and continues his septic and sexual relations with her. Most men touch their penis several times a day while urinating, and yet I dare say few of them ever think of washing it, no matter how dirty their occupations, before thrusting it into the parturient canal at night. Men sometimes have sexual relations with their wives within a week or two after confinement, the woman develops symptoms of puerperal fever, and the doctor is puzzled to explain the cause, and perhaps lays it to the breasts, or catching cold, or to auto-infection.

The patient does not have many opportunities for infecting herself, but the methods she employs are calculated to be very successful. Most women think any old rags are good enough to receive the lochial discharge, and this they must be prohibited from doing. She must also be discouraged from using the family sponge, to bathe herself with. The surgeon would do well if he ordered all wash-rags and sponges used for such purposes burned before labor begins, for they will turn up unexpectedly a dozen times during confinement, unless they are entirely out of reach. Only recently I had prepared a parturient woman in a thoroughly aseptic manner, she found it necessary to visit the closet, and while there the waters broke and began dribbling away, when she promptly applied the bath-room sponge to the vulva, where I found it an hour later. These may seem to be little things, but if we expect to do aseptic surgery and get desirable results, we must be externally vigilant.

Vitiated air may greatly increase the predisposition or be a direct cause of puerperal infection. Here, in our northern climate, houses are built with a view of keeping out the cold, and incidentally of course fresh air. In the winter double doors and windows are put on. The natural vitiation of the air is increased by an untrapped or defective drain connected with the sewer. The British Registrar-General's report shows that the smallest number of deaths from puerperal fever every year, for the last twenty-five years, has always been in August, when all the windows are open, and the defective drains have least chance to do harm; and the largest number of deaths has always been in January, when, the windows being closed, sewer-gas laden with bacteria, remains for a long time undiluted in the house. Puerperal fever is relatively common in the bedrooms of the rich, where the elegant marble basin is directly connected with the city sewer. The lowest death-rate ever yet attained is in the Sloane Maternity, where there is absolutely no plumbing in the building, and at the Preston Retreat, where a steam fan blower forces half a million cubic feet of fresh air every hour into the lying-in wards.

IMPORTANCE OF FRESH AIR AND EXERCISE IN THE TREATMENT OF TUBERCULOSIS.

By A. H. STEWART, M.D.,

RICHMOND, KY.

The unmistakable evidences of pre-existing and progressive weakness in the vital and physical energies of the body organisms found in the vast majority of cases of tuberculosis, and the fact that the disease progresses just in proportion to the extent of this weakness makes plain the line of hygienic treatment to be adopted. Reinforce these weakened energies with an abundance of fresh air, sunshine, wholesome nutritious diet, and, in suitable cases, moderate judicious exercise should be the watchword all along the line. As to the value of these measures there is quite a unanimity of opinion, except as to the amount of exercise that should be allowed in connection with the fresh-air treatment, and on this point there is quite a diversity of opinion. Many of those who use the terms physiological weakness and physiological exhaustion synonymously, and consider exhaustion to be a necessary consequence of any form of exercise, require absolute rest in all classes of cases; while many of those who believe that strength comes through stimulation, and that exercise is the best form of stimulation, take the opposite view, and favor active exercise in nearly all cases, regardless of the physical condition of the patient. Now, it is apparent that there is some truth and much error in each of these propositions, and that the logical course to pursue is to regulate the exercise to suit the physical condition of each individual case. The most positive indications for rest are pyrexia, hæmoptysis, and extreme debility, because: *a*, except in some hectic conditions pyrexia indicates progressive inflammation at the seat of the disease in the lungs; *b*, hæmoptysis indicates disintegration of tissue and giving way of vessel walls, small or large, according to the extent of the hemorrhage: and *c*, debility indicates exhaustion of the physical forces, potential and kinetic, through fever, exercise, or defective assimilation, all of which conditions are best treated by absolute quietude and rest in bed. The first two because, like similar conditions elsewhere, they need rest, which in these conditions is best secured by reducing the number of heart-beats, lowering the force of the blood-pressure, and checking the flow of blood to the parts by absolute quietude, and the last because in this way the tissues are given an opportunity to recuperate their exhausted forces. But this does not indicate that absolute rest should be continued after these ends have been attained, nor does it indicate, especially in the last case, that after partial recovery the process may not be facilitated by moderate judicious exercise, limited always, however, to the needs of the body. In this connection it is important to make a distinction between cell weakness, defective cell energy, or imperfect metabolism, and cell exhaustion, as these terms are ordinarily used and understood. That high fever and excessive exercise are potent factors in bringing about exhaustion through consumption of the forces and energies, and that the logical way to check this is to arrest the cause, are too well understood to even be mentioned here, if it were not for the fact that in many

cases the process is carried so far that the basis from which these forces draw their supply are so far injured that no amount of rest will restore them to their normal condition. Something similar to this occurs in the case of old ulcerated sores. The minute histological structures that form the line of demarcation between the healthy and diseased tissue are neither dead nor alive, nor will any amount of rest restore them to their normal state. There is too much vitality to permit disintegration, but not enough to allow new blood to come in and impart new life. The surgical treatment in such cases would be to remove all the tissue not susceptible of being restored to healthy vitality, or stimulate by counter-irritants, or by friction and massage force the blood into the parts and stimulate them to normal activity; while nature's method would be to increase the quantity and quality of the blood, strengthen the heart, and force this new blood into these parts, and thereby drive back the broken-down *débris*, and heal by granulation. This is largely the condition that prevails in many cases of chronic tuberculosis, and this is the way a cure is brought about by nutritious diet, the dry rarefied air of high altitudes, and pulmonary gymnastics. A vastly increased amount of fresh air is brought to the lungs, much of which finds its way to unventilated nooks and crevices, where it imparts its oxygen to, and takes up carbonic acid from, the residual air in the air-vesicles, and forces oxygen into the blood circulating in the pulmonary capillaries. The large amount of new blood thus brought to the margins of the ulcers forces its way into the weakened, sluggish tissues, facilitates expulsion of broken-down *débris*, and hastens the healing process by throwing out protoplasmic granular processes, which by degrees encroach upon and fill up the diseased area.

But still there is another general morbid condition in which a distinction should be made between cell weakness and cell exhaustion as the terms are ordinarily used, and that is in the strumous or tubercular diathesis. Here the defects seem to be rather a stagnation than an exhaustion of the energies and forces. The lymph possesses but little vitality, moves sluggishly along the lymph channels, and is easily obstructed in its course. The capillary circulation is often without force or potency, the villi often fail to absorb, and the tissues fail to appropriate and to assimilate the nutriment intended for them. It is this character of cell weakness that is found in a large number of consumptives. It is this weakness that enables the organisms of the disease to make such rapid inroads into the tissues, and it is this weakness which is not benefited by rest, except so far as it has been further reduced by fever or exercise that is to be overcome in the treatment of this disease. It is in this class of cases, when there is no fever and no great amount of debility, that a favorable change is often brought about by stimulation through such moderate, judicious exercise as will gradually increase the force rather than the frequency of the pulsations, and the depths rather than the number of respirations. In this way oxygenation and assimilation are facilitated, and all the metabolic processes are carried on more perfectly and energetically, and the tissue resistance thereby proportionately increased. The average daily consumption of oxygen during quietude being estimated in round numbers at thirty thousand cubic inches, and the average increase in the number of respirations while standing up, over the number while lying down, being estimated at one-third, there are, other things being equal, a daily increased consumption of ten thousand cubic inches of oxygen while standing up over that consumed while lying down. But after reducing this even one-half, for sleep and repose, there is still an excess of five thousand cubic inches, which counts for much when an invalid is starving for oxygen. Besides, the amount of oxygen taken in is augmented nearly or quite as much by the increased depths as by the increased number of respirations during ordinary, and especially during pulmonary, gymnastic exercises. It is pulmonary rather than bodily exercise and an increase in the depth rather than in the number of respirations, then, that is wanted. This accounts in a measure for the benefits derived from high altitudes, from horseback riding, and, to some extent, from carriage driving. But in the latter cases the change of the position of the body (without body exertion) brings it into contact with more air, or at least it brings the body more forcibly into contact with the air, the same as does increased velocity of the air, and this of itself stimulates respiration and increases the amount of air consumed. The main object, then, being to catch and consume as much available air as possible, the essential idea intended to be conveyed when contending for out-door open-air exercise is the living and revelling in the fresh air, rather than the taking of active exercise therein. But just to the extent that the volume of air consumed can be increased by sitting up, by moving leisurely about, or by being conveyed, as in a carriage or on horseback, from place to place without drawing on the weak stock of energy in bank, to that extent it is beneficial. Consequently a careful invoice of the energy in bank to the credit of the tissues should be taken by the physician and the patient before any exercise is recommended. Some of the indices to this are the number, force, and volume of pulsations, number and depth of respirations, the elevation of temperature, and the nervous susceptibility of the individual. The amount of stock, too, may be tested by drawing on it cautiously and temporarily, by going up and down a flight of stairs, lifting weights, or walking briskly a short distance. In each case the amount of energy exhausted may be approximated by the increased pulsations and respirations, the increased elevation of temperature, and the perceptible amount of exhaustion to the patient.

A temperature of 100° F., and especially of over 101° F., contraindicates any kind of exercise. Rapid, feeble pulse, quick, shallow respirations, much increased by slight exertion, and much exhaustion after slight exertion, indicate great feebleness, and call for much caution and discretion in deciding upon the character and kind of the exercise to be recommended. Some may recline on a couch, or sit up in a chair in the open air; others may, if they wish, play checkers or dominoes, read a magazine, or do light needlework; while others may go riding or driving, and even hunting, fishing, rowing; tennis and ball-playing may be engaged in by those who enjoy such sport, and those able to engage in them. Manual labor on a farm, driving a market-wagon, or canvassing, may be permitted by the more robust, not so much for financial as for physical gain. Hill climbing, flower, plant, and mineral gathering—something to make out-door exercise pleasant—are especially to be recommended. Those who look upon exercise as a task to be performed, and think the earlier it is commenced and the sooner completed, and the more energy expended the better the task will be done, usually return from such exercise entirely exhausted and much worse off, physically, than before they started. This is why a morning or evening's walk, horseback ride, or buggy drive, do not count for much. Instead of building up, they often exhaust the vital and physical energies on account of the haste that is taken and energy expended during such exercise. Fresh air is not a luxury to be indulged in only occasionally, at brief periods, and at long intervals, but to the consumptive, whose natural supply of fresh air is greatly reduced on account of defective pulmonary expansion, and whose blood is hourly becoming more and more impoverished, it is a constant necessity.

For him to seek fresh air at such periods is like starting on an important mission and making one step forward and three backward. The final result—complete failure—would inevitably be the same. In living

out of doors, however, some consideration must always be given to the most inclement weather, it is true ; yet if properly prepared with water-proof, shoes, and wraps, the climate out doors must be very bad indeed if it is worse than badly ventilated houses. In any event, one cannot ordinarily wait to see if it is going to clear up, or if the sun will come out, while such enemies as the tubercle bacilli are invading, or even threatening to invade, the tissues, when the most effective method of obstructing their progress is by building fortifications out of the invaded or threatened tissue by filling them with new blood through fresh air and wholesome exercise. Fortify the strength and increase the number of the phagocytes in the blood, array them in one solid phalanx against the enemy, and in a large per cent. of cases they will come off victorious. If they cannot annihilate the enemy they can stop their further progress, imprison them in cavities, or encapsulate them in a net-work of fibrous connective tissue so effectively that they cannot make their escape. In climates where the atmosphere is dry and pure the patient should camp on the field at night ; he should pitch his tent in the open air so that the enemy cannot take advantage of stagnant air in a close room, in which they like to carry on their deadly work, to recuperate their weakened forces and be ready to renew the attack in the morning. If the house must be occupied even during the night, it must be well ventilated from cellar to garret, and from centre to circumference. The bed is to be placed, not in the draught, it is true, but away from stagnant corners, where the patient can get the benefit of all the fresh air in the room. It has been well said that the greatest trouble about draughts is that they are not large enough. What constitutes a draught when the air enters at a small opening may not be even a gentle breeze when all the doors and windows are thrown open. The inequality in the temperature of the inside and outside air gives rise to draughts. The cold air on the outside rushes in through every little crevice to take the place of the evaporated, rarified air on the inside.

Perhaps rather thin flannel underwear is best at all seasons of the year while taking out-door exercise, as it will take up moisture without becoming damp and sticky, but even this should be changed frequently.

When it is absolutely impossible to take out-door exercise on account of the extreme inclemency of the weather, pulmonary gymnastics should be persistently carried on at home. Indeed, a consumptive should allow no day to pass without such exercise, even when other exercise is taken.

Constancy and regularity in such exercise can only be carried on under the supervision of a physician. The patient can no more be trusted, though his life be at stake, without some oversight by others, than an athlete preparing for the world's championship contest can be trusted to take the proper exercise without a competent trainer. The will cannot summon courage sufficient to meet such extra requirements of the body. With the body erect, as it should always be, and the head rather thrown back, full, deep, prolonged respirations should be taken for five to ten minutes, three to six times a day. The arms should be slowly raised from the sides in a circle till the hands meet above the head during deep inspirations, and then be lowered in the same way during exhalations. This should be repeated from six to ten times, then the arms should be raised and brought forward in a circle till the palms meet in front on a level with the forehead while the lungs are being inflated, then lowered or moved as far backward as possible during expiration ; or better still, after the lungs have been fully inflated, while the arms are elevated or in front, the breath should be held while the fullest possible circles are made with the arms in every direction, tapping the chest occasionally with one and then with the other open hand, while weights, dumb-bells, or Indian clubs should be lifted from the floor by the side, or with arms outstretched till they are brought together, either in front on a level with the forehead, or above the head during inspiration, and then lowered during expiration. At least one-half hour should be devoted to such exercise every morning and evening, even when other exercise is taken, and two or three times as often in the open air when little or no other exercise is taken. It is well always to have some primary work on physical culture at hand, and study the various movements as they are described and illustrated.

These exercises should always be carried on in the open air, or where the windows are open. By such respiratory gymnastics the lungs are thoroughly inflated, the air reaching many nooks and crevices filled with stagnant residual air and lurking bacilli. For this reason, if for nothing else, the inhalation of non-irritating, volatile substances should always be recommended.

In order to interest the patients and insure their hearty co-operation, it is recommended by some to attach great importance to the medicaments used, and sometimes to use complicated apparatus in order to throw as much mystery around the treatment as possible. But usually this is not best. To intelligent patients it is always best to be frank, speak plainly, and tell the truth. Indeed, if a little pains be taken to explain the nature of the lesions, their course, and the effect of fresh air and constant inflation of the lungs, it is much better.

Complicated instruments should usually be discarded and irritating medication never used. While it has not been demonstrated that any specific influence is exerted on the tubercle bacillus by any method of antiseptic inhalation treatment so far used, yet it is agreed, with singular unanimity, that when non-irritating balsamic or volatile substances are used there is a decided amelioration of many of the most aggravating symptoms of the disease under such treatment. With almost equal unanimity, too, it is agreed that great benefit is also derived from continued deep inspirations, whether the inhaled air contains any medicament or not.

While I have unbounded faith in the ultimate success of the antiseptic inhalation medication, and believe that even now much good is derived from it, yet for the present the question of paramount interest is continued respiratory gymnastics, frequent, full respirations, constant, complete inflation of the lungs.

For this purpose some of the simple, cheap, vest-pocket inhalers, made of glass or hard rubber, are usually to be preferred to the more expensive, complicated atomizers and inhalers, and even to the much-lauded but cumbersome and unsightly muzzles to be worn over the mouth and nose. Evans's glass inhaler, which has a dilated end for the sponge, or Dennison's hard-rubber inhaler and exhaler, which has a roll of blotting-paper for medication in one end, will answer every purpose. They can be carried in the vest pocket, and a few drops of some non-irritating volatile or balsamic preparation, as terebene, oils of fir-wood, southern pine, or eucalyptus, thymol, creosote, or compound tincture of benzoin, dropped on the absorbent and inhaled ten to fifteen minutes six to ten times a day. It is not necessary, nor even advisable, that the medicine should be renewed every time the inhaler is used. Usually five to fifteen drops of one or more of the above preparations once a day will be sufficient. Whenever pain or any disturbance is caused by the use of any preparation, the quantity should be reduced, or its use discontinued altogether, for a while at least. Usually any existing nasal post-pharyngeal catarrh, laryngitis, or bronchitis, is very much benefited, and even the tuberculous process in the deeper portions of the air-passages are often benefited ; cough is relieved, rest secured, appetite increased, and the condition of the patient much improved. The healing process is

facilitated by the increased amount of blood brought to the lungs.

No plan of hygienic treatment is complete without the daily bath—not for cleanliness alone, but for the purpose of stimulating the activity of the skin and superficial blood-vessels, as well as to remove all waste matter from the surface. To most persons a bath at night in cold or tepid water is the most agreeable. Others, more delicate, receive great benefit from the sponge-bath with a damp cloth, and then rubbed down briskly with a crash towel. Some prefer the bath in the morning, to which there is no objection. The one essential condition is that some kind of a bath or rub down be taken daily. Where a thorough bath is taken at night in water containing a little borax or aqua ammonia, it is well in many cases to anoint the patient thoroughly with fresh, clean lard, thoroughly beaten till it has the appearance of cream, or with cotton-seed oil, petroleum, or cocoa-butter. Whatever ointment is used should be delicately perfumed. The hands and feet should be kept warm, the bowels moved at least once a day, and rest and sleep at night secured. The uniform success attending the treatment of tuberculosis in sanitariums established for that purpose, a number of which are in successful operation in this country and in Europe, especially those conducted on the cottage plan, is due to the intelligent, systematic combination of the hygienic, dietetic, and medical treatment carried on at these institutions. Under the influence of the compressed, rarified, and medicated air-baths, nutritious diet, fresh air, and wholesome exercise, a large per cent. of patients improve rapidly, for a while at least, without any medicine whatever. For except in the best equipped hospitals it is here that the pneumatic cabinet and all the needed appliances are the most perfectly arranged and systematically applied to the needs of each individual case.

A BRIEF STUDY OF THE PHYSIOLOGICAL EPOCHS THAT PREDISPOSE TO INSANITY, WITH OBSERVATIONS ON THE MANAGEMENT OF EACH.[1]

By WILLIAM PHILIP SPRATLING, M.D.,

MEDICAL SUPERINTENDENT, CRAIG COLONY, N. Y.

The grave responsibility of treating insanity in its incipiency rests in a greater degree on the physician in general practice than on the specialist in the diseases of the mind. Budding mental infirmities almost invariably come first under the observation and care of the family physician, and it is difficult to properly estimate the greater measure of success that can often be obtained when insanity is early recognized, its significance appreciated, and the disease properly treated. It is because of these indisputable facts that I feel justified in bringing this subject to the attention of a representative society like this.

Charles Mercier, an English alienist of distinction, sums up the causes of insanity in a concise and pleasing manner as follows: "Insanity is, in mathematical terms, a formula of two variables; that is to say, there are two factors and only two in its causation, and these factors are complementary. Both enter into the causation of every case of insanity, and the stronger the influence of one factor the less of the other factor is needed to produce the result. These factors are heredity and stress."

Now, while heredity and stress are words that admit of great breadth of meaning, as they must to include all cases of insanity, they constitute a very acceptable dual head under which to crystallize the inexhaustible list of active and contributory causes that give rise to mental degeneration. Moreover, we will find, when we come to study the various states of mental instability that arise directly out of the physiological epochs, that heredity and stress, with their subdivisions, constitute the only etiological factors. There is no variation from this.

There are certain well-defined physiological epochs that appear at fixed periods during the growth and development of the body. These epochs are all strictly physiological in the order and nature of their occurrence, save one, the epoch of heredity, and that may be said to be pathological, or patho-physiological. These epochs are six in number, and I have designated them as follows: 1, The Epoch of Early Childhood; 2, the Epoch of Puberty; 3, the Epoch of Maternity; 4, the Epoch of Heredity; 5, the Epoch of the Menopause; 6, the Epoch of Senility.

The epoch of early childhood covers the period from the end of the sixth month to the seventh year. Strictly speaking, the period should be regarded as an indirect epoch only, since insanity occurring so early in life is extremely rare. There are, however, frequent cases in which the accidents and incidents of early life facilitate the establishment of insanity in after-years.

The epoch of puberty in the female extends from the thirteenth to the fifteenth year; in the male from the fourteenth to the sixteenth year.

The third epoch covers the entire child-bearing period, from the fifteenth to the forty-fifth year. Insanity occurs more frequently during the first than during the last half of the period.

The epoch of heredity, I believe, has not had special attention called to it by writers in this country. A French authority, Régis, uses the term "Phrenasthenia" to include all forms of inherited insanity. The epoch of heredity is an important and variable one, and embraces that critical period in the life of every individual whose ancestors were accustomed to exhibit evidences of insanity on reaching a certain age.

The fifth epoch embraces the climacteric, and extends in women from the forty-third to the forty-fifth year. Rare exceptions may extend the line a little either way. It is, perhaps, the best-defined epoch of them all, inasmuch as the changes that occur during this period are most perceptible and oftenest lead to mental instability.

The sixth and last epoch, that of senility, or old age, needs no particular designation, but it is of interest to note that when the preceding epochs were not strictly physiological in their occurrence, that pathological conditions of mind are more apt to be encountered on the approach of extreme old age.

Returning now to the first epoch, that of early childhood, let us briefly review the accidents and incidents that are common to this period, and that may serve to render the child a fit subject for mental disorder in the future.

The first, and undoubtedly the most important of these, because it is the most universal, is dentition. Gowers is authority for the statement that one-eighth of all cases of epilepsy begin during the first three years of life; and adds that with rickets as a combining cause seventy-five per cent. of all cases of epilepsy that begin during the first three years of life are due to infantile convulsions ascribed to teething. Here the vicious tendencies of an inherited taint change a perfectly physiological process, that ought to be free from danger to the child, into a period fraught with influences of a most pernicious kind. Syphilis, chronic alcoholism, insanity, or epilepsy in the parent, stamp on the nervous system of the child a congenital taint that unfits it to cope with the serious disturbances that mark the steps of growth and development. Genuine epilepsy probably never occurs in the first instance out of difficult dentition alone. Epileptiform convulsions, however, do quite frequently arise from this cause, and these in time take on all the characteristics of genuine

[1] Read before the Medical Society of the County of New York, September 24, 1894.

epilepsy, and finally become fully established as such. That insanity often follows in the footsteps of epilepsy is a matter of common knowledge. In the *Journal of the American Medical Association* for August 18, 1894, Wilmarth, gives some interesting facts regarding idiocy, epilepsy, imbecility, and insanity, as he studied them at the Pennsylvania Institute for Feeble-Minded Children. Out of 1,000 cases admitted to the institution he found 322 suffering from illness of such a nature as to require medical treatment and care prior to being sent from home. That is to say, 322 cases out of 1,000 were affected in such a manner as to indicate that medical treatment would possibly have brought about recovery.

This excluded of course all cases of congenital troubles that it was not possible for medical skill to relieve. It also excluded all cases in which congenital defect was even noted before the sixth month, that is, just prior to the commencement of dentition. But more important still, he found that the disorder in 75 cases out of the 322 was recorded as having begun during the spasms of dentition. Up to the sixth month 2 were recorded as having thus begun; between the sixth and twelfth months, 29; between the twelfth and eighteenth months, 25; between the eighteenth and twenty-fourth months, 19. In these cases, likewise, hereditary taint was not perceptible prior to the first dentition. The growth of the child's brain is rapid, and anything that interferes with its nutrition is a serious matter. The period of most active growth is over at the seventh year.

Besides dentition a great variety of other causes are constantly acting on the organism of the young child that threaten to disarrange the adjustment of the more highly developed parts. Among these may be mentioned traumatism, blows and falls on the head, infantile paralysis, effects of excessive heat, mental shock, fevers of specific origin, diphtheria, whooping-cough, strictures and malformations of the genital organs.

It is not necessary that I should attempt to review the approved methods of treatment in all these cases. Such knowledge belongs to every physician. I desire to emphasize only my belief that in a vast number of selected subjects some of the physiological processes of childhood become distinctly pathological, and that prompt, active, and intelligent treatment will often avail in saving the mental life of the child.

Next comes the period of puberty. The excito-motor exaltation of the nervous system during the first dentition has also its parallel in the explosive condition of the nervous centres, in the higher plane of the cerebral activities, during the evolution of the generative functions, and the sexual divergence or the epoch of early adolescence. This period is, therefore, the second great trial of the constitutional powers of the subject, and is especially prone to reveal any dormant inherited vices. Indeed, such epoch may be characterized as one of the search-lights of the science of psychiatry, since it serves to reveal weak spots in the mental organization of every individual. The mental disorders that so frequently develop at this age are due to indirect stress of internal origin.

The period of puberty is fixed in the female between the thirteenth and the fifteenth years, and in the male from fourteen to sixteen. Pubescent insanity, however, may develop anywhere between the ages of fifteen and twenty-two. The pubescent epoch is attended with more danger to the female than to the male; the reason of this is obvious. In the female the period consumed in passing through this stage is much shorter than in the male. The male attains maturity gradually, whereas the female acquires it almost at a bound; consequently the shock is greater. The insanity of this period in the male is characterized by a silly, childish disposition; depression that may terminate in profound melancholia, mental enfeeblement, bodily inactivity, and later on by systematized delusions that pertain chiefly to self. The manner of the origin of mental obliquity at this period is explained as follows: The period of puberty in the male is the transitional stage from boyhood to manhood. The psychical and physical life of the boy are threatened with extermination, as they have reached a period when carelessness, lack of judgment, natural egotism, and the sportive tendencies of youth are about to be superseded by the attributes that characterize the man. The conflict is inevitable, the result of the union of two opposing forces giving rise to a display of the mental symptoms above described. If the boy is not handicapped by inherited or acquired vicious tendencies that serve to lower nerve-tone he will escape mental blight at that time. But if he inherit a predisposition to insanity, to alcoholism, to epilepsy, or if he begin to masturbate, evidences of grave mental disorder quickly become apparent.

Insanity in the female at this period is essentially an acute neurosis. As before stated this is due to the shorter, sharper transitional period through which the girl is forced to go in order to reach womanhood. Acute mania is the form of insanity that is most frequent. The preponderance of the maniacal states over states of depression is also a feature of the insanity of the puerperal period.

After the acute stage has somewhat subsided evidences of intellectual derangement appear, and fixed delusions become manifest. Sometimes, however, melancholic perversions are noted, and marked by delusions of persecutions and fears of impending evil.

Hallucinations of the special senses appear in about one-fourth of the cases in both sexes. Visual and aural hallucinations predominate, and sixteen per cent. of such cases entertain ideas of poisoning, and religious delusions are not uncommon. The prognosis in such cases is very good, when uncomplicated by hereditary taint, since nearly eighty per cent. get well. The management and treatment of insanity in the pubescent stage consists in the early removal of the patient from home, should prejudicial influences exist there. Nourishment should be given in an easily assimilable form, and the secretory organs should receive special attention, since they are peculiarly liable at this period to sluggish action. Sleep should be secured by open-air exercise. Narcotics and sedatives should not be given unless imperatively demanded; only when insomnia has existed for several nights in succession, in spite of an observance of the above means, are sedatives admissible; of these we have many to choose from and I need not enumerate them here.

The menstrual irregularities of this epoch will require special attention. In cases where the rate of development has been excessively rapid, and where the nutritive and assimilative capacities have been overtaxed by the demands of the growing organism, anæmia of a most troublesome form is often encountered. Here a strictly hygienic regimen is to be enforced, and iron, preferably in the form of the carbonate, freely given. The extract of nux vomica and rhubarb in pill form are of service, and I have seen excellent results follow the use of malt extract in combination with the compound syrup of the phosphates, in such cases.

The third epoch embraces the child-bearing period. The puerperal state, in the wider sense in which Repping uses the term, has more important relation to the causation of insanity than the other physiological periods, not excluding those of the climacteric and of the senile evolution. During pregnancy, during labor itself, which is sometimes accompanied by extreme transitory frenzy, and during lactation, the mental life of the woman is in peril. Insanity occurring during pregnancy is more frequent in mothers who are about to bear illegitimate children. The elements of grief and remorse, as they affect the emotional sphere, account for this fact. The mental anomalies of this period vary all the way from simple morbid appetites

to well-marked melancholia with well-marked suicidal impulses. The transitory frenzy occurring during labor, mentioned above, is dependent either on the extreme agony of childbirth, or it appears as the forerunner of delirium of the puerperal state. Infanticide and suicide are acts common to the subjects of this condition. Hereditary predisposition increases the gravity of the attacks of this period. Insanity following childbirth may develop suddenly after delivery, or may come on gradually after evidences of nerve exhaustion; when it begins suddenly it almost always takes the form of acute mania. Out of sixty-eight puerperal cases studied by Bevan Lewis, forty-five, or sixty-six per cent., suffered from mania, while only thirty-three per cent. showed states of depression. The symptoms in acute mania comprise intense excitement, great incoherence, continuous garrulity, and a dangerous explosiveness, which is manifested in acts of violence and destructive tendencies. Visual and aural hallucinations are frequent, being present in about eighteen per cent. of such cases. Delusions of a varied character are present in over sixty per cent. Impulsive acts are common, leading most frequently to attempts at suicide. The etiology of this disorder is interesting, but cannot be discussed here. The treatment is most important; in the majority of cases it is a good practice to begin it with a saline aperient. Search for the cause of fever. It may be due to putrescible matter in the uterine cavity, or to septic absorption through a raw surface of a rupture or tear, or it may be due to peritonitis, phlebitis, or an inflamed mammary gland. If it is due to septic absorption, measures must be promptly instituted to check further infection; a vitiated condition of the blood may demand the free use of iron, but none of the chalybeate preparations should be given until all traces of acute excitement have subsided.

The infant must be early removed from the mother's care. The mother's diet should consist of milk, beef-tea, broths, and eggs, and should be administered in small quantities at frequent intervals.

To secure sleep chloral, potassium bromide, sulfonal, or paraldehyde should be given. My personal preference is paraldehyde in two-drachm doses, or more if required, given in a small quantity of port wine. Warm baths often suffice to produce refreshing sleep, and, when practicable, deserve a trial before medicines are given.

Insanity occurring during lactation differs in no essential feature from that which occurs just after childbirth.

The fourth epoch, that of heredity, requires only brief mention. The form of insanity that develops at this period is determined very largely by the form of insanity with which the ancestors suffered. And it is especially prone to occur in the offspring at nearly or about the age at which it became manifest in the parent. An instance recently came under my observation in which the members of a family for four generations suffered more or less from insanity just as soon as they reached a certain age. In the first generation only one person was insane, in the fourth, four are now or have been insane.

The fifth epoch embraces the menopause. The psychic manifestations attendant upon this critical period are well marked. For women who have an inherited tendency to mental disease, or who have suffered from previous attacks of insanity during one of the former epochs, this period has added dangers. The type of insanity common to this period is constant; painful mental states invariably prevail.

Doctor Skae characterizes the alienation occurring at this period as follows: "A monomania of fear, despondency, remorse, hopelessness, passing occasionally into dementia." Fifty-five per cent. of cases at this period are of the depressed type. Acute maniacal conditions sometimes exist. The suicidal impulse is frequent, more than one-half possessing it. The prognosis may be considered as favorable, if inherited weaknesses do not prevail, and if the subject has not previously been insane.

The treatment consists mainly in a tonic regimen, out-door life, strict attention to dietetic matters, and change of environment. Anæmia must be met by the administration of iron, preferably the ammoniated citrate of iron, and in combination with small doses of arsenic. Such patients often require artificial feeding, and we have four methods of accomplishing this to choose from. Sleep usually has to be secured by artificial means—chloral hydrate in a single large dose, or paraldehyde, is to be preferred.

The sixth and last epoch is senility, and I will make only brief reference to it. The most common form of insanity at this epoch is senile dementia; it is questionable, however, whether we are justified in regarding this form of dementia as a separate and distinct psychical disorder, dependent upon pathological conditions of its own. Senile dementia is really nothing more or less than the physiological loss of mind. Retrograde changes occurring in the brain, in the form of widespread atrophy, give rise to the symptoms common to extreme old age.

Senile mania and senile melancholia occur as distinct disorders. In senile mania we usually have simple maniacal excitement without any obvious involvement of the intellectual faculties. Such attacks are marked by incessant garrulity, severe disturbance of the emotional sphere, restlessness, persistent insomnia, incoherence of speech, and outbursts of passion. When uncomplicated by hereditary taint, or previous alcoholic excesses, such cases usually recover. But they must not be mistaken for one of a series of excitements that usually terminate in dementia.

Senile melancholia is a frequent accompaniment of the physiological involution of the brain on the advent of senility. The tendency to suicide is strongly marked in this condition, seventy-nine per cent. of such cases showing this tendency. But little can be said of the treatment of these cases. The most important thing to do is to maintain so close a supervision of the patient that self-destruction will be impossible. The most satisfactory results I have obtained from the use of any drug in treating the insanities incident to old age have come from the use of opium. Nature in the second childhood seems as susceptible to its influence as in the first childhood. When there is great restlessness and fixed insomnia, the use of opium, beginning with small doses, has a happy effect. Moreover, in persons who have lived the allotted time of threescore years and ten, the danger of establishing the opium habit is not to be feared so much as if the patient was still in the prime of life.

Antivivisection and Polo-playing.—We notice that the editor of *Our Dumb Animals* is starting a war on polo-playing. Polo-playing, according to our contemporary, is "a meaner sport than prize-fighting. It is," he says, "cruel and brutal, and one which ladies that profess to respectability and refinement ought to be ashamed to countenance." This same gentleman, who thus attacks polo, offers a prize for persons who detect evidence of vivisection, and gives over his own signature a most extravagant eulogy of a certain cholera and dysentery syrup, which, he says, "cured a lady at Rye Beach, who was not expected to live through the night," and "cured a lady in Maine, who was in great agony, which the doctor did not relieve."

A Prominent Sanitarian asserts that if all the cholera germs in the world were dumped into Lake Michigan, Chicago would be in no danger. We are a little in doubt whether this assertion is meant to be considered a tribute to Chicago's greatness, or the diluent power of Michigan water.

ACUTE ŒDEMA OF THE LARYNX, WITH REPORT OF A CASE.*

By F. E. HOPKINS, M.D.,

NEW YORK.

ASSISTANT SURGEON TO THE MANHATTAN EYE AND EAR HOSPITAL (THROAT DEPARTMENT); ASSISTANT SURGEON TO THE NEW YORK EYE AND EAR INFIRMARY (EAR DEPARTMENT); FELLOW OF NEW YORK ACADEMY OF MEDICINE.

ACUTE œdema of the larynx is, fortunately, a rare affection, so rare and of such gravity as to warrant the reporting of the following case:

On January 24, 1895, I was called to attend J. G——, whom I found suffering from a mild attack of la grippe, which was epidemic at that time. The patient, a stout, florid male of Irish birth, about forty-eight years of age, a dealer in masons' supplies, had been drinking both spirits and malt liquors for two years, and growing stout, until he had reached a weight of two hundred and thirty-five pounds. His average weight for the six preceding years had been somewhat less than two hundred pounds. His attack of la grippe proved a mild one, its most prominent symptom being a constant spasmodic cough, without any marked pulmonary lesion. I saw him but three times. On the 29th he seemed quite well, and he was left with a caution against exposure. The patient had always enjoyed good health, and finding confinement to the house irksome, returned at once to business. Four days later I was called to see him again, when he was suffering from acute amygdalitis and pharyngitis. This yielded promptly to treatment and the patient had so far improved, that on my visit on February 4th I told him that I would not call again for two days. We were at that time having the coldest weather of an unusually cold winter. The patient again recklessly exposed himself, and I was hastily summoned early on the morning of February 6th. He had passed a restless night and I found him sitting in a chair, breathing with some difficulty; his voice was hoarse and he coughed, but without expectoration. Examination of his chest revealed no lesion. His temperature was 100° F. and pulse 112. The posterior wall of pharynx and the larynx were much congested, the aryepiglottic folds and the ventricular bands were somewhat swollen. I prescribed warm steam inhalations, gave tincture aconite internally, and directed that he make frequent use of hot nourishing fluids.

The symptoms grew rapidly worse and by 7 P.M. his condition was truly alarming. He was restless, incessantly moving about and demanding that the windows be opened, that he might get more air. He was cyanotic and his expression anxious. His respirations were short and rapid, all the accessory muscles being brought into the utmost activity. Inspiration was stridulous, expiration not so much obstructed, while the voice was nearly suppressed. Swallowing was all but impossible, apparently more from mechanical obstruction than from pain, though the latter was considerable. His temperature had risen somewhat, being 102° F., pulse, 130. On examination with the laryngoscope, nothing but the epiglottis could be seen. This appeared enormously enlarged in every direction—doubtless the apparent elongation was due to the angle at which the tumefaction forced it to stand. The œdema was greatest at the sides, and this had the curious effect of doubling the epiglottis upon itself. Its upper free edge was not œdematous, for anatomical reasons pointed out by Hajek [1], but it was intensely congested, and the mucous membrane covering it seemed thickened and loose. On each inspiration the lateral edges of the epiglottis approximated posteriorly, and then this thickened and loose mucous membrane on the upper free edge collapsed, falling in like a valve, narrowing still further the small chink through which the patient breathed. I conclude from this appearance that the arytenoids and aryepiglottic folds, which I could not see, and owing to the intense dyspnœa I did not dare attempt to explore with my finger—were so swollen that the epiglottis in its unnatural position rested upon them, and the patient got air only through the curious opening just described. A condition of the epiglottis similar to this has been reported by Baron.[2]

Earlier in the day I had planned to intubate, should that promise to afford relief, but after this view of the parts decided to scarify instead. Guided by the mirror I made deep incisions first upon the right side of the epiglottis and then upon the left. I was surprised to see my incisions as gaping clefts in a mass of gelatine, followed by little hemorrhage or exudation of serum and no apparent shrinking of the œdematous tissue. The excitement of the patient and his struggle for breath were making him so restive that it became apparent that if anything were to be accomplished by scarification it must be immediately. Accordingly further free incision was made into the tumid mass. This was followed by more free bleeding, and evidently some of the fluid entered the larynx, as a spasm was at once excited and attended by most frightful dyspnœa. I seized a bistoury, intending to plunge it into the trachea. This is not so simple a matter when the patient, a man of two hundred and thirty-five pounds, is standing in bed and tearing wildly at his throat. After watching the patient a moment, and being convinced that he was getting air enough to prevent immediate suffocation, I did what I could to calm him and sent for Dr. J. W. Hurley, the nearest physician, to assist in performing tracheotomy. The severity of the spasm gradually subsided and the patient could breathe with less terrific effort. A hypodermic of morphia was administered which aided still further in the relief of spasm of the larynx. Leeches were applied over the larynx and following them, a cold coil.

When the excitement had sufficiently subsided to allow of noting the pulse it was found dangerously rapid and weak, and free stimulation was required for some days. The coil was worn almost continuously for three days, and the air of the room kept constantly moistened. The œdema of the epiglottis continued sufficient to prevent a view of the arytenoids until the fourth day after the scarification, when they, as well as the aryepiglottic folds, were still œdematous.

The patient had been ill to such a slight degree, up to the time of the laryngeal symptoms, that my attention was not called to the condition of his kidneys. No specimen of urine could be secured on the night of the 6th, the urine being suppressed. The first specimen of urine was small in quantity, of dark color and high specific gravity, containing albumin and casts. It was noticed by the 8th that his lower extremities were œdematous, and he became somewhat delirious. Casts were found only at the first examination, and the albumin disappeared from the urine in two weeks from the onset of the laryngeal symptoms. The convalescence was slow. Although the element of danger involved in the laryngeal stenosis seemed to have passed in about three days, the patient did not recover sufficient strength to allow of his return to business for two months from the beginning of the original attack.

I shall but touch upon the history of the subject, as this has been so exhaustively treated by many writers, and shall consider only acute œdema affecting the upper part of the larynx.

According to Mackenzie,[3] the ancient authors show no clear knowledge of the disease. Morgagni in 1765 gave the first correct account of it, founded upon post-mortem examinations, but the literature of the subject dates from its scientific portrayal by Bayle, in 1815. In 1852 Sestier, who had gathered a vast amount of statistical evidence, issued a standard treatise, and this author had since been quoted by every writer who has treated the subject with anything like thoroughness.

That the disease is a comparatively rare one is shown by the fact that the Index Medicus for 1885 had no

* Presented as a candidate's thesis to the American Laryngological Association, and accepted by the Association at its Seventeenth Annual Meeting, June 17, 1895.

reference to a case of this affection; also by the investigation of Peltesohn,[4] who found that of 5,161 patients treated in a clinic for diseases of the throat and nose, between April 1, 1887, and June 1, 1889, there were only eight cases of acute œdema of the larynx. Of these seven were men between twenty-one and forty-eight years of age, and one a woman fifty eight years of age. Seven occurred in connection with local inflammatory conditions. The etiology could not be determined in the eighth. Systemic disease could not be discovered in any of the cases. This number of cases is less than one-fifth of one per cent., and these were from a throat clinic. The per cent. in a general clinic would be small indeed. Peltesohn also examined the records of autopsies made under charge of Virchow, between 1873 and 1878, with the following results: In 3,887 examinations, œdema of the larynx was noted 210 times—149 in men, 40 in women, and 21 in children. The majority of men were between the ages of eighteen and sixty years, and women, between twenty-one and fifty-four years, while 13 of the children were less than five years of age. Forty-four cases were due to local, and one hundred and thirty-six to systemic disease. It is thus seen that men are much more liable to the affection than women, and that relatively few cases occur in childhood.

Etiology.—The causes of the affection are many and various. The influence of age and sex is marked, as appears from the above statistics, while those of Sestier are similar. The influence of exposure to cold is seen in the fact that the greatest number of cases occur during the winter season. Recent writers seem inclined to the theory of infection as a common cause. Exposure to cold, or any similar condition which reduces the resisting power of the mucous membrane of the larynx, makes possible the very entrance of streptococci or pneumococci, bacteria which are at all times to be found in the mouth and nose. Such is the opinion of Garel,[5] Barjon,[6] and Kuttner,[7] and bacteriological examinations, as reported by them, have shown the presence of the bacteria named. Primary erysipelas of the larynx, first alluded to by Radcliffe,[8] but thoroughly investigated by Massei,[9] belongs to the diseases of infectious origin and falls into this category. Massei is quoted by every recent writer upon the subject of œdema of the larynx, and has the support of the best authorities. Virchow[10] says that these acute cases of œdema of the larynx, on closer analysis, prove to be cases of erysipelas of the larynx. Anatomically, erysipelas is but an œdematous swelling. At first Massei was inclined to base his diagnosis upon the presence of Fehleisen's coccus, but recent investigations[11] have proven that it is impossible to differentiate between this and staphylococcus pyogenes aureus; and he now depends upon three principal points in the clinical aspect of the case: the rapid dysphagia, the character of the œdema—as its livid color and easy displacement—and the remitting temperature.

Acute œdema may occur during the course of systemic disease. Some renal disease is mentioned by writers as the one most often thus complicated; but this must evidently be rare, for Mackenzie[3] examined the larynx in two hundred cases of Bright's disease without finding œdema present in a single instance. Albumin is often present during a grave case of œdema of the larynx, but according to Barjon[6] this is to be looked for as a usual accompaniment of the local disease, and the urine is free from albumin within two, or at the latest three, weeks. This was true in my case, the albumin disappearing in about two weeks. It may occur in the case of small-pox, typhoid fever, diphtheria, scarlet fever, or any of the exanthems.[12] A curious neurotic affection closely connected with urticaria, and characterized by the sudden appearance of circumscribed areas of œdema in different parts of the surface of the body, has been described by Osler in a paper read before the Philadelphia Neurological Society.[13] The larynx may be invaded by the same process. The term angioneurotic œdema has been applied to this condition. A case of this kind was reported by Pryor.[14] The patient, a healthy male, thirty years of age, a dentist, developed a sudden œdema of the larynx without ascertainable cause. This reached a dangerous degree of infiltration, but under active treatment subsided, and the man resumed work within forty-eight hours of the attack.

Cases af acute œdema following the use of iodide of potassium have been reported by Avellis[15] and by Baumgarten[16] and others. I have seen one such case in a woman of about thirty years of age, in whom so small a dose as twelve grains three times a day for two days produced decided symptoms. It may occur during the course of rheumatism affecting the crico-arytenoid articulation. It may occur from traumatism, scalds, the presence of a foreign body, the swallowing of corrosive poisons, or the inhalation of flame.[17]

Recently several cases have been reported as following or complicating la grippe. Dr. Robertson[18] reports three such cases in children, the youngest eight months old, the oldest seven years. Rhu[19] reports three cases in adults. Tucker[20] describes a case of septicæmia occurring during the prevalence of la grippe, complicated by œdema of the larynx. In this case the true cords were much involved in the œdematous process. The cases following la grippe should perhaps properly be classed with those due to infection. I do not know of any bacteriological examination in this connection, but all the conditions necessary to infection are present, the patient being debilitated by disease and the bacteria present in the throat ready to set up infection. Indeed, several of the cases reported followed a faucial or pharyngeal inflammation. One by Rhu[19] complicated a posterior pharyngeal abscess and terminated fatally. Serous effusion into the larynx may also occur as the result of an obstruction to the return of venous circulation, caused by the presence of an aneurismal or other tumor in the cervical or upper thoracic region;[12] and in the various forms of cardiac disease, and the direct complication of specific forms of inflammation of the larynx, as syphilis, tuberculosis, and perichondritis.[21]

Pathology.—The disease is due to a transudation from the blood-vessels into the submucous connective tissue, and this transudation is most abundant in those parts in which there is the most connective tissue, that is, in the aryepiglottis folds, the ventricular bands, and the anterior face of the epiglottis to within a short distance of its free edge.[1] It is exceedingly rare that this process involves the true vocal cords or extends to the subglottic region. This character of the œdema produced varies greatly. In those cases which have been called primary erysipelas of the larynx, the exudation is superficial and the parts are easily drained of the contained serum by scarification. According to Massei, as quoted by Garel, the appearance is quite like that of a nasal myxoma in color, and the tumor, easily displaced, is of a trembling gelatinous consistency. In the most acute and rapidly fatal cases pure serum only is found.[3] It must be in these cases that scarification is followed by such prompt, not to say magical, results.

In certain cases the network of submucous connective tissue holds the imprisoned serum so tightly within its meshes, that, as Bayle expressed it, it cannot be squeezed out. This, however, does not prevent the œdema from gradually emptying itself through the punctures made in scarification.[22] It is in these cases that the immediate results of scarification are disappointing. One may be led by his reading to anticipate prompt relief to the dyspnœa upon incising the œdematous tissue, but in this form the patient may for a brief period be thrown into a still more alarming state. The flow of blood following incision may enter the larynx and excite spasm so severe as to threaten instant suffocation. In the phlegmonous variety, which, according to Kuttner,[23] may be regarded as a

later stage of the serous, the transudation changes to sero-purulent, or becomes purulent with abscess formation. In this event the abscess is usually limited to one side.[12] Mackenzie says the pus is always diffused, circumscribed abscess never occurring as a sequel of acute inflammation of the larynx. Post,[24] however, reported an autopsy upon a case in which he found fibrinous exudation in the larynx with points where suppuration had occurred.

Symptoms.—The attack may be ushered in by a chill, but the temperature following is not usually high; 101° F. was noted in my case. This chill may simply be the result of exposure to cold. Cough, hoarseness, and pain are observed, but the symptoms of prime importance are those referable to respiration. Owing to the rapid infiltration, especially in the serous form, respiration is early obstructed, and the infiltration often advances so rapidly that within twelve hours of the attack the patient's condition becomes one of great gravity. Inspiration is at first more obstructed than expiration, as the swollen tissue tends to roll in, and, valve-like, to close the larynx, while expiration is not so much interfered with.

The rapid progress of the disease is well illustrated by the case reported by Edes.[25] The patient, an athlete in excellent health, aged thirty-five, after exposure to cold had a chill followed by faucial inflamtion. A few hours later he suddenly sprang out of bed, said he was suffocating, ran a few steps, and died within a few moments. At no time previous to the final seizure had there been any complaint of difficulty in breathing, nor had dyspnœa been noticed by the attendants. The autopsy showed a marked degree of œdema of the submucous connective tissue of the epiglottis, aryepiglottic folds, and cords.

The voice, at first not much altered, becomes gradually hoarse, and later may be lost or only a hoarse whisper, due to the overhanging masses of swollen tissue, the interarytenoid tumefaction, or to infiltration of the muscles themselves. The cough is unproductive. It seems to be an effort to rid the throat of what the patient describes as some foreign body. Pain is not always severe, but an effort to swallow, especially if the epiglottis is involved, causes distress, chiefly because of the mechanical obstruction. The patient assumes the sitting posture, seeking some support for his hands, that the auxiliary muscles aiding respiration may be brought into the fullest possible activity. The face becomes first flushed, then cyanotic, and the whole body trembles from the excitement and the muscular tension required to sustain respiration. The symptoms are aggravated at night, for, as the patient falls asleep, the conscious effort to aid respiration which has been maintained during the day is suspended. The urine is scanty and of high color, and in the grave cases contains albumin.[6]

Diagnosis.—In acute laryngeal stenosis we have to determine whether the given case be one of œdema or of foreign body in the larynx. The history of the case will usually afford some aid; but the laryngoscope is to be relied upon not only for differential diagnosis, but at the same time to reveal the degree of the stenosis. One also gains a knowledge of the location and character of the œdema, whether it be superficial serous exudation or the intense congestion indicative of phlegmon. Palpation has been employed, but it is brutal and not devoid of danger, as it may excite dangerous spasm of the larynx. Barjon mentions an interesting point in external palpation. If one seize a healthy larynx between the thumb and fingers, and pressing it backward upon the spinal column, give it a lateral movement, there is produced a very perceptible crackling sound, caused by the spring of the cartilage against the vertebra. In laryngeal œdema the infiltration of the posterior portion of the larynx forms an isolating cushion which prevents this crackling sound.

Prognosis.—This is always grave except in those rare cases in which the œdematous process is limited, as to one side of the larynx. Even the apparently mildest case may develop a rapid œdema which proves fatal within a few hours. Much depends upon the stage at which the case comes under observation, and the promptness and vigor with which measures for relief are employed. Those cases of superficial serous œdema, if seen early, offer better hope of recovery than those of the phlegmonous variety. Primary œdema is less likely to prove fatal than secondary. Prospect of recovery in the latter depends in part upon the general disease or the local condition with which it is associated. Secondary œdema coming on in connection with typhoid fever and small-pox is likely to be fatal.

The period of the most urgent symptoms does not usually last beyond three or four days. If the infiltration has not reached a suffocative degree within that time it will probably not be the direct cause of death.[21] There, however, remains the danger of complications—pneumonia, septicæmia, or cardiac involvement—and in any case of continued dyspnœa the convalescence is likely to be prolonged because of the patient's great prostration.

Sestier, quoted by Mackenzie,[3] found that the affection proved fatal in 158 out of 213 cases in spite of tracheotomy performed thirty times. In the 55 cases which recovered tracheotomy was performed twenty times. Bayle's[9] statistics are much less favorable, as he reports 17 cases with 16 deaths. It would be interesting to know if the mortality is less at present by reason of treatment. I have not found statistics of any large number of cases, but those I have gathered from medical journals of the past few years make a much better showing. They are, however, not numerous enough to allow of any definite deductions. There is the suspicion, too, that only the more favorable results secure publication.

Treatment.—After attempting to read even one of the exhaustive and laborious German monographs upon the subject of œdema of the larynx, in which the history of the subject, its etiology and bacteriology reveal a faithfulness of research which excites one's admiration—and proves at the same time a trifle appalling—it is a relief to come to the subject of treatment.

Notwithstanding the gravity of the condition which confronts one, and the conflicting ideas on etiology, there is a reassuring definiteness in the plan of treatment; and in a portion of the cases the response to vigorous and well-timed measures of relief is prompt and gratifying. If a case be seen at the beginning of an attack, the treatment for a severe acute inflammation of the larynx is to be recommended. The inhalation of warm medicated vapor, the use of diaphoretics, the maintenance of the patient's room at an equable temperature, 72° F.—with the air moistened by the vapor of boiling water; and at a later stage the application of leeches over the region of the larynx, to be followed by the continuous use of the cold coil. The sucking of pellets of ice is also to be recommended. Upon the appearance of œdema, however, scarification with the laryngeal lancet should be performed. By the aid of the laryngoscope this can easily be done, for, in spite of the struggle for breath, patients readily and quietly submit to the operation. In those cases of superficial œdema the relief which follows scarification is spoken of as little less than magical; but it is well to remember that the particular case before one may be that of more solid œdema, in which the exuded serum is held tightly imprisoned in the meshes of the connective tissue, so that the serum drains off but slowly and little relief immediately follows the scarification. Indeed, spasm of the larynx may be excited and for a time the patient's condition seem even more critical. This method of affording relief was first employed by Lisfranc in 1823,[3] but the operation fell into

disuse. It was first done in this country by Buck,[26] who reported cases in 1848. He was led to the adoption of the method by his own reasoning, not being aware that it had previously been employed. During a period of eleven months he saw the surprising number of eight cases. Five of these he scarified, and all of them recovered.

Lennox Browne[21] recommends the hypodermic injection of muriate of pilocarpine, one twelfth to one-fourth a grain, and the *International Medical Magazine* for 1892, Vol. I., contains a report of two cases in which the use of one-eighth grain hypodermically was promptly followed by the constitutional effects of the drug, and within an hour there was marked subsidence of the laryngeal œdema. In serous œdema Garel[5] recommends the application of pure tincture of iodine after cocainizing, and reports good results from its use.

Various drugs, as cocaine, astringents, etc., have been sprayed into the larynx, and while these may be of some avail, one should not temporize too long in their use, but employ scarification, which is to be repeated if necessary. The recurrence of œdema, however, is less likely to take place if one persists in the use of the cold coil and pilocarpine. The temperature is not usually sufficiently elevated to call for attention. It should, however, be watched as affording a warning of the beginning of complications. Of these, pneumonia and septicæmia are the most frequent.

In case all the measures suggested fail to afford relief, then tracheotomy should be done, nor should this be delayed till the patient has become so exhausted as to render the operation almost hopeless. Intubation[27] has been performed in several cases, and will have a limited application in this affection, especially in those rare cases where the cords or the parts immediately adjacent are principally involved. One should be prepared either to intubate or perform tracheotomy, as may seem indicated. The exhausting character of the affection must be borne in mind, and feeding, stimulation, and tonic medication receive careful attention, both during the attack and during the convalescence, which in many cases is prolonged.

INTESTINE CONSTRICTED BY VERMIFORM APPENDIX—OBSTRUCTIONS—OPERATION—RECOVERY.

By DWIGHT H. MURRAY, M.D.,

SYRACUSE, N. Y.

On Friday, June 14th, at 5 P.M., I was called by Dr. J. A. Belch to see Wesley D——, aged seven and a half years. The following history of the case was given:

On Monday, June 10th, he had eaten very heartily of "potted meat;" on Tuesday he vomited and purged five or six times, which was followed by a very severe pain in the bowels, so that "he danced about the house," as the mother expressed it. This vomiting and pain continued until Thursday, June 13th, when the father consulted Dr. Belch at his office, thinking it unnecessary for the doctor to call at the house, saying that it was a bilious attack.

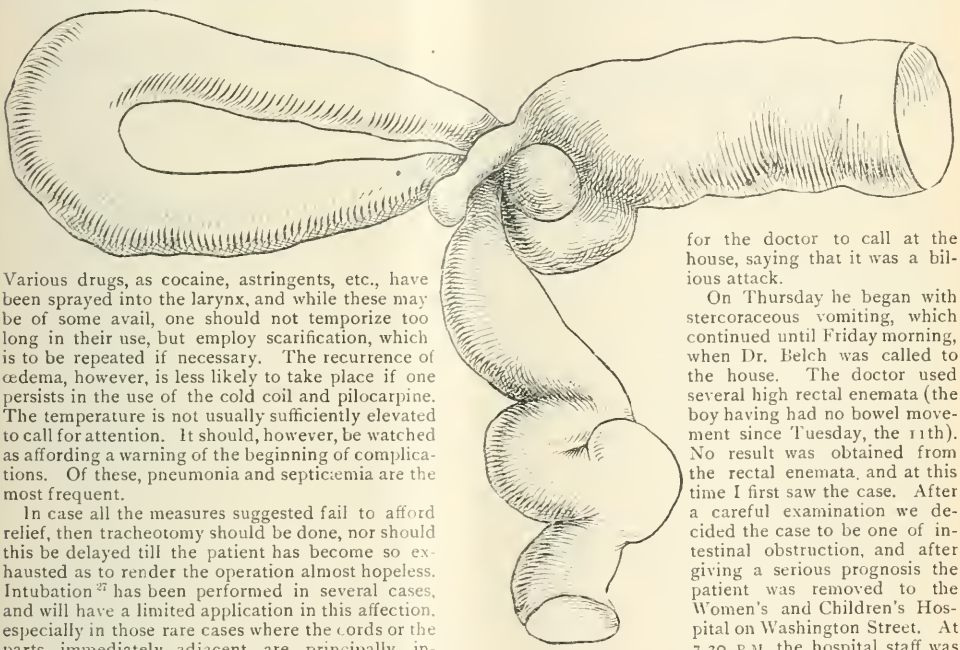

FIG. 1.

On Thursday he began with stercoraceous vomiting, which continued until Friday morning, when Dr. Belch was called to the house. The doctor used several high rectal enemata (the boy having had no bowel movement since Tuesday, the 11th). No result was obtained from the rectal enemata, and at this time I first saw the case. After a careful examination we decided the case to be one of intestinal obstruction, and after giving a serious prognosis the patient was removed to the Women's and Children's Hospital on Washington Street. At 7.30 P.M. the hospital staff was called together and after consultation it was decided to defer operation until morning, continuing high rectal enemata of glycerine and saturated solution of magnesium sulphate, alternating each hour, and applying hot stupes externally. At 8.30 P.M. a large quantity of stercoraceous material was vomited, after which the patient rested quietly all night.

At 8.30 A.M. on the 15th, the hospital staff, with the addition of Drs. Heffron, Alfred Mercer, and Belch met, all preparations having been made for operation. The boy having passed a comfortable night, and his general condition being good, he was placed upon the table at

9 A.M. A careful examination was given under an anæsthetic; no tumor or other evidence of obstruction except constipation being present, it was advised to give a dose of calomel and wait a still longer time. Several high enemata were given through a long, stiff, rectal tube, with no result except the clear water returning. At 2.30 P.M. ten grains of calomel were administered, stupes continued, and three high enemata were given before 9 A.M., Sunday, the 16th, no further vomiting occurring. I again saw him at 9 A.M. on the 16th, and feeling that no further time should be lost called the staff together, and it was agreed to operate, which I did at 12 M., assisted by Dr. Breese; anæsthetic given by Dr. Wynkoop. Present, Drs. A. B. Randall, R. C. McLennan, F. W. Sears, Alfred Mercer, and J. A. Belch.

Median incision was made, the presenting gut held by Dr. Breese. I followed the gut down to the right iliac fossa, where I found a hard mass, which was brought up into the incision and proved to be the obstruction, which was caused by the vermiform appendix wound around a loop of the ileum, over and under, the end of the appendix having passed upward from the back side of the mass between the ileum and the caput coli. The end of the appendix was enlarged and slightly adherent to the ileum by newly formed adhesions. The constriction was very tight, producing complete obstruction to the gut. It was with difficulty that the appendix could be pulled away from the ileum so that the constricted loop of the intestine could be drawn through the knot that had been tied. When this was done, however, the appendix lay free in the abdominal cavity, the end of it being clubbed, then a narrow portion under the enlargement, and the remainder being of normal size, as shown by Figs. 3 and 4. The appendix was two inches in length, and was removed at a point one-half inch from the caput coli. Figs. 1 and 2 show, respectively, the front and back views of the obstruction as it existed at the time of opening the abdominal cavity.

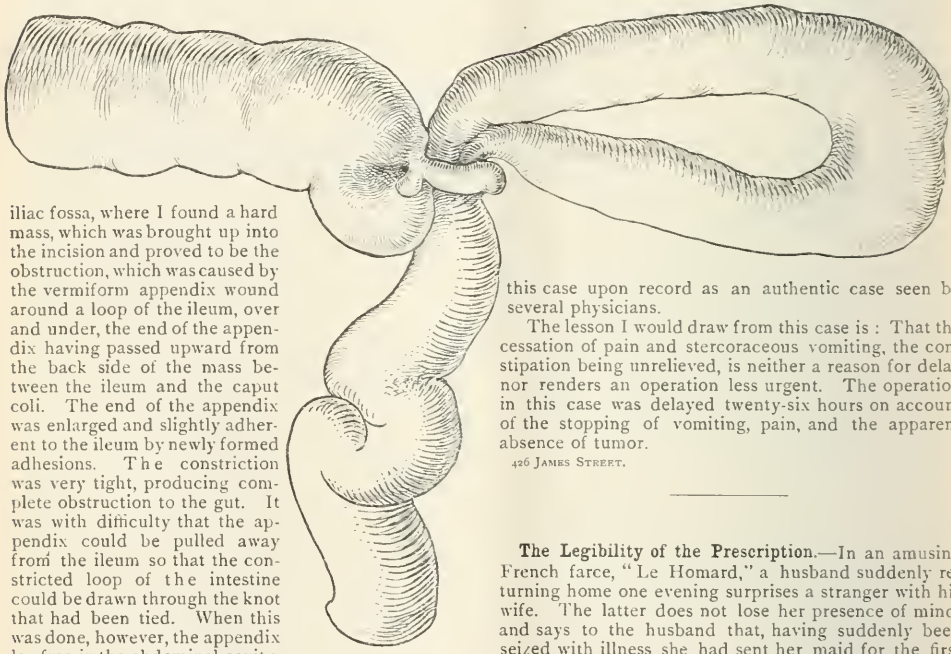

FIG. 2.

FIG. 3.

FIG. 4.

The time of operation was twenty-five minutes; the recovery from the anæsthetic was good, no vomiting. At 2.45 P.M. he passed one ounce of urine and had a small movement from the bowels, which was thin and dark brown in color; at 3.45 an involuntary movement of the same character. Between this time and 6.10 P.M. he had three other movements; at 2 A.M. a formed movement, and from this time to the time of his discharge from the hospital there were no bad symptoms of any kind, the temperature only going to 101° F. at 9 in the forenoon after the operation, falling to normal at 5 the next morning, never going to 100° after that. He was discharged from the hospital July 5th, entirely recovered.

This form of intestinal obstruction, so far as I have been able to find from the literature, is very rare, if not unique. Dr. Treves in his work on intestinal obstruction states that this form of obstruction has been claimed to have existed, but that it is difficult to credit it. On this account I feel that it is important to place this case upon record as an authentic case seen by several physicians.

The lesson I would draw from this case is: That the cessation of pain and stercoraceous vomiting, the constipation being unrelieved, is neither a reason for delay nor renders an operation less urgent. The operation in this case was delayed twenty-six hours on account of the stopping of vomiting, pain, and the apparent absence of tumor.

426 JAMES STREET.

The Legibility of the Prescription.—In an amusing French farce, "Le Homard," a husband suddenly returning home one evening surprises a stranger with his wife. The latter does not lose her presence of mind, and says to the husband that, having suddenly been seized with illness she had sent her maid for the first available doctor, and that this gentleman was the doctor. The husband thanks the gallant for his speedy appearance, and asks if he has already prescribed anything. The gallant, who, of course, is not a doctor, tries to make himself scarce; but the anxious husband insists on having a prescription, so that the Galen, bathed in cold perspiration, is compelled to give one. The husband casts a glance at it; it consists of wholly illegible marks. "And will the chemist be able to read that?" asks the husband, shaking his head. "As if it were print," asseverates the false physician, again trying to make his escape. The husband, however, adjures him to remain, and holds him fast till the maid returns from the chemist. In a few minutes she makes her appearance. The Galen prepares himself for a catastrophe. No. The maid brings a phial of medicine, a box of pills, and some powders. "Did the chemist give you those?" demands the Galen in bewilderment. "Certainly." "On my prescription?" "Of course it was on your prescription," replies the astonished maid. "Has the chemist made some mistake?" interposes the troubled husband. "No, no," our Galen hastens to reply; but he contemplates the medicines for a long time and becomes lost in reverie.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

OYSTERS AND TYPHOID FEVER.

PROFESSORS HERDMAN and Boyce recently presented to the British Association for the Advancement of Science a report upon the cultivation of oysters and their relation to typhoid fever and other diseases. This report is the result of an experimental inquiry into the effect of oysters of various external conditions, including pathogenic organisms. This country, which is such an extensive consumer of oysters, ought not to be indebted to European scientists for knowledge regarding the relation of oysters to infective diseases. For some reason, however, not very much has been done here in this direction, except to investigate certain special epidemics. The facts established by Professors Herdman and Boyce, therefore, should be of much practical value to oyster growers and oyster consumers. The observations of the gentlemen in question showed that oysters were very much benefited by having plenty of air, or, in other words, by being supplied by water in which there is an active change produced by tidal or other currents. They established the fact that oysters can be made to grow fat or to become sick and die, according to the kind of food with which they are supplied. The oyster is, for example, very much harmed by the action of sugar, and it does not thrive upon oatmeal. The oyster is injured also by the micro-organisms that develop in stagnant water; on the other hand, it seems to tolerate sewage very well, and it was found that it even has a certain capacity for clearing contaminated water of its sewage. It can even live for a prolonged period in water, made quite opaque by the addition of fæcal matter. It was further established, though this fact was already known, that the oyster takes up the micro-organisms that are in the water about it. They are found, however, more plentiful in the pallial cavity than in the rectal, showing that the organisms are, to a certain extent, digested. The typhoid bacilli, in particular, were found to decrease in number as they passed down the alimentary canal. The most important practical point, perhaps, reached by the experimenters, was the determination of the fact that oysters could be practically cleansed of all their pathogenic germs by a suitable process of feeding, that is, by supplying them with a sufficiency of clean, aerated water. Professors Herdman and Boyce found, as others have done, that the typhoid bacillus does not grow in salt water.

RAILWAY DISCOMFORTS.

THE report, which we give briefly in another column, of the International Conference on Railway Hygiene, suggests that very much helpful work might be done by organizations of this kind. We have plenty of societies of railway surgeons, and we have a copious supply of insurance companies of all kinds. We have also very many enterprising railway companies, but there is no organization which takes upon itself the task of supervising or suggesting measures for the sanitary improvement of railway travel. We, in America, boast often of the superiority of our cars, and of our tracks, and of the swiftness of our express trains, but those who travel much cannot fail to see there are numberless deficiencies, which a little more intelligence and care on the part of railways might correct. The ventilation, for example, of our so-called parlor-cars is admitted to be an utter failure. The cars are close and stifling in winter, and hot beyond endurance in summer. There seems to have been no real intelligence or special skill in ventilation applied to the architecture of the American parlor-car. The question of smoke, and dust, and cinders, is one also which deserves attention, from a sanitary point of view. The harm done to the eyes and to the mucous membrane of the nose and respiratory tract, by the constant inhalation of more or less carbonaceous particles, is certainly very considerable, and one that must eventually amount to something to the commuter. The question of the water-supply upon cars and of the food furnished upon them and at railroad stations, is also one that well deserves the supervision of the sanitarian. In fact, if a national congress on railway hygiene were organized in this country, we feel sure that it would be able to secure a great many interesting papers, and would, perhaps, stir up a sentiment in favor of better and more sanitary conditions of railway travel, the result of which would be to keep a great many of the Americans, who now go to Europe, at home.

TWO MILLIONS OF PATIENTS.

THERE is a doctor in St. Louis who says that he has treated two million cases of insanity in the last thirty years. This statement, we understand, was made while he was serving in the capacity of an expert on the witness stand. He subsequently affirmed the correctness of the statement in a letter to the *Medical Weekly*.

Two million cases in thirty years means 66,666 cases every year. This means 182 cases a day. Allowing that the doctor, with this active practice, slept only six hours and worked the remaining eighteen seeing his two million cases, this would give him about ten cases of insanity every hour in the day, or one every six minutes. This, of course, is quite a possible feat, but it shows an extraordinary activity on the part of the St. Louis mind. The more fairy-like side of the tale comes out when one studies the source from which the two million cases of insanity came. If the statistics of this country are correct, there have not been two million cases of insanity in all United States, within the last thirty years. There may be uncounted millions of

lunatics, however, in Missouri, being so near to Kansas. But upon the whole we fear that the esteemed expert must have been suffering somewhat from an expansive delusion in regard to his experience in insane matters. We have heard of people who, having had a few minutes interview with a lunatic, felt as though they had seen sixteen, and no doubt this sense of numerical exaggeration which attacked the St. Louis doctor, was due to some such subjective influence as this. Still, it would have been more to the credit of Southwestern medical expert testimony, if arithmetic were a branch of science carefully studied. At present it seems as though there is one medical expert who lisped in numbers, because the numbers came.

A MENACE TO PUBLIC HEALTH.

The Board of Health of this city has recently had its attention directed to several cases of flagrant violation of the sanitary code through the transportation in public conveyances of patients suffering from contagious diseases. The danger of spreading disease by such means would seem to be apparent to even the most ignorant of laymen, yet it is said that many physicians are guilty of this practice. Nearly every week, so it is stated by Dr. Benedict, chief inspector of contagious diseases, patients are brought from their homes to the Willard Parker Hospital in public cabs, and on inquiry it is found in many cases that this is done on the advice of the family physician. In other cases the physician has simply directed that the patient be taken to the hospital, but has given no directions as to how the transportation shall be effected. The friends then have the alternative of taking the patient in a public carriage or, worse yet, in a street car. If a cab is used, the vehicle is seized upon arrival at the hospital and disinfected, and the danger to others is comparatively slight; but when the patient goes in a street car, there is practically no limit to the number of persons exposed to contagion both during the transit and afterward.

This could be avoided by merely notifying the Health Board, when an ambulance will be sent to transport the patient. When so simple a remedy is at hand, it seems strange that any physician would permit himself, or his patient, to incur the expense of a carriage, expose others to the risk of contagion, and moreover violate a law, for which there is a penalty of $250 and imprisonment.

MESCAL BUTTONS.

Drs. D. W. Prentiss and Francis P. Morgan publish, in the *Therapeutic Gazette* for September 16th, an account of some experiments made with the mescal button, a vegetable substance of which the botanical name is *Antralonium Lewinin*.

The attention of the medical world was first attracted to this drug by Lewin, but, aside from his observations, little attention has been given to this substance. The mescal button is obtained from a plant which grows in a valley of the Rio Grande, in Mexico. The tops of the plants when dried constitute the commercial form of *Antralonium Lewinin*. They are brownish in color circular, and from one to one and a half inch in diameter. The button is hard and can be pulverized in the mortar with difficulty. In the mouth, however, under the action of the saliva, it swells and rapidly becomes soft, giving a nauseous and bitter taste, with a marked sensation of tingling in the fauces. Two or three alkaloids have been abstracted from this substance, as well as some resinous bodies. The mescal button is said to be used by the Indians in connection with some of their religious ceremonies. Upon certain festal occasions, the Indians seat themselves in a circle around a large camp fire; then they begin to swallow the buttons, one after another, until ten or twelve are taken during the course of the night. A sort of reverie or quiet intoxication is produced, and the participants in the ceremony continue under the influence of the button until sundown or noon of the next day.

The therapeutic investigations made by Drs. Prentiss and Morgan consisted simply in the administration of buttons in different doses to six different adults, noting the effects. Not more than three or four buttons were taken, as a rule. The result produced seemed to be in all cases somewhat alike. The most striking was the development of visions, ranging from ill-defined flashes of color to most beautiful figures, landscapes, dances, etc. The principal feature of the visions was the color effect. The pleasurable effect of the drug seemed to be mainly due to the development of these entrancing visions. The effect upon the muscular system was depressing, and there was at no time any general stimulation or intoxication, such as is produced by alcohol. Dilatation of the pupil was well marked in all cases, and this persisted for twenty-four hours. Partial anæsthesia of the skin was present in three of the cases; the heart action, if anything, was somewhat depressed; the respiration was unaffected; the stomach was sometimes irritated and nausea was felt. The drug is not a sleep producing one, but has rather the contrary effect. No constant disturbance of the pulse, skin, or the temperature was noted. The drug seems to have an effect to some extent resembling that of Indian hemp, and in a slight degree that of cocaine. According to the description as cited above, its effects are on the whole somewhat unique. We ought to add that Lewin reports one case in which the drug was taken experimentally by an adult, and in which it produced a rapid rise of pulse, headache, and difficulty in respiration, which was so great that the patient's life was imperilled and he became unconscious.

It is possible that when the various constituents of the drug are obtained, and their effects carefully studied, we may have in the mescal button an addition to our Pharmacopœia of some value.

The State Board of Health of Missouri has issued regulations regarding the requirements of persons who intend to study medicine. The minimum requirement recognized by the Board is one which demands the presentation of a diploma of graduation from a good literary or scientific college or high-school, or a first-grade teacher's certificate.

BRAIN INJURY AND CONSCIOUSNESS.

The article in the Medical Record, of October 12th, by Dr. Hrdlicka, upon a case of extensive traumatic brain lesion, affords an interesting commentary upon the question of the amount of injury which the brain can receive without consciousness being lost, or the mental functions being very seriously impaired. This subject has been occupying the attention of some of our contemporaries in the last few weeks. In a recent murder trial, it seems that a woman was shot with a pistol while in bed, and it is claimed that she rose, spoke to her husband, and walked through several rooms to the rear of the house. The prosecution assert that, with such a wound as she received, she could not have spoken or walked, but would have relapsed at once into unconsciousness. The description of the wound seems to show that the bullet must have passed pretty nearly horizontally through both frontal lobes. All surgical writers agree as to the great tolerance of the brain to injury, when in particular the latent portions of the brain are affected. In connection with the particular medico-legal case referred to, comes up the history of the celebrated Yankee who, through a premature explosion, received a tamping-iron in his head, destroying a considerable portion of his frontal lobes without very serious after-effects. In Dr. Hrdlicka's case, however, there was some serious immediate effect due to the shock, as there was also in the tamping iron case, and it is, so far as experience goes, extremely unlikely that any human being can sustain the effects of the concussion and shock, that would be produced by a ball passing through the brain, without, at least, a temporary disturbance of consciousness.

News of the Week

Medical Society of the State of New York.—The following gentlemen constitute the business committee for the next meeting of the State Society, to be held in Albany during the last week in January: Dr. H. R. Hopkins, of Buffalo, Chairman; Dr. Nathan Jacobson, of Syracuse; and Dr. J. M. Winfield, of Brooklyn. Members desiring to present papers are requested to promptly notify the Chairman of this Committee. Addresses have been promised by Professor William Pepper, of Philadelphia; Professor James H. Etheridge, of Chicago; and President Eliot, of Harvard University, who will speak on the subject of "Medical Education of the Future."

Johns Hopkins University, Baltimore.—Dr. W. W. Russell has been appointed Associate in Gynecology, and Dr. Thomas S. Cullen Instructor in Gynecological Pathology, in the Johns Hopkins University, Baltimore. Dr. Otto Ramsay has gone to Freiburg for a year to study gynecological pathology under Professor E. Ziegler.

The Hartford Medical Society have purchased a centrally situated building site for the location of the Society building, for which Mrs. Mary C. Hunt left them a legacy of $20,000, provided they acquired a site, free from encumbrance, upon which to erect a building exclusively for the use of the Society, as a memorial to her husband, the late Ebenezer K. Hunt, M.D.

Errata.—In Dr. Hayward's article on "Honey in Erysipelas," read *heat* swelling instead of *heart* swelling. In Dr. Baruch's article, on top line, second column, p. 472, read *borine* instead of *bovine*. On fifteenth line from bottom, second column, p. 474, read "has rarely failed," instead of "rarely fails."

Railway and Marine Hygiene.—Among the numerous conferences of an international character which have been held during the fall, is one which took place at Amsterdam, September 20th, and which was concerned with the hygiene of railway and marine travel. The conference was started by certain Dutch officials, and the gentlemen taking part were mainly from Holland and England. The question of the examination of eyesight of railway employees was the only one that seems to have been extensively discussed. The speakers reported a very great improvement in the methods of such examinations, and also in the extent to which they were applied. In France, England, and Holland eye-tests are required, but not in Belgium. Dr. Zwaardemaker, of Utrecht, read a paper upon the importance of the acoustic examination of railway servants, and urged that every railway man should have at least one ear possessing normal acuteness. Papers dealing with the question of medical aid on railway trains were read, and also papers on "Overwork," on "Traumatic Hysteria," the "Disinfection of Stations and Restaurants."

Telling the Story of Surgical Progress.—A weekly religious paper, *The Independent*, has recently published a series of articles by a number of prominent American surgeons, of which the object is to show to the public how great a thing is modern surgery. There is no question whatever as to the wonderful progress made in surgery in modern times, but we observe that modern surgery has never lacked sweet singers to chant its praise, as the mighty wheels of the chariot of its progress go rolling along. We believe thoroughly in allowing the public to estimate the medical profession at its full worth, but it sometimes seems as though the exploitation of the wonders of surgery was a little overdone, the result being, that as soon as a person has any ailment of any part of the body, the people at once want to have it cut out.

Typhoid Fever in Washington.—The Health Office of Washington states, October 11th, that an epidemic of typhoid fever exists in that city. During the last week, at least six hundred cases were reported. The epidemic is attributed to the lowness of the water in the Potomac River (from which the city is supplied), and to the use of well-water in families.

Congress of Physiologists.—The International Congress of Physiologists held its annual meeting at Berne, Switzerland, on September 9th, 10th, and 11th. Professors Goltz and Ewald showed a dog all of whose spinal cord had been removed, from the middle dorsal region downward. The removal had been performed at three different operations, during a year and a half, and the animal had survived the last operation two

years. There was a degeneration of the muscles below the line of the lesion, but the animal had retained power over the sphincters, both of the bladder and rectum, and since the last operation had given birth to pups. Dr. Demoor, of Brussels, showed that an actual anatomical change takes place in the processes of the cortical nerve-cells in animals to which a strong dose of morphine or chloral hydrate has been given. Professor Herzen, of Lausanne, read a paper in which he brought evidence to show that the spleen exerts an important influence on pancreatic digestion. Professors Hürtle and Mosso showed a new apparatus for the determination of blood-pressure in man. Dr. Jacquet, of Basle, read a paper on "The Influence of Cold Baths on the Circulation in Fever." He showed that in fever the red blood-cells disappear from the systemic veins and collect in the loin and abdominal veins, and that cold baths prevent this, while antipyrin does not. Professor Mosso read a paper on "Respiration and Circulation in Man at High Altitudes." These studies were made at a height of 15,000 feet. Mosso found that at this height, during repose, respiratory exchange is less.

The Congress accepted an invitation from Professor Foster to hold its next meeting at Cambridge. Dr. Bowditch, of Boston, was elected one of the presidents.

Medical Morals.—The *British Medical Journal* contains a medico-ethical column, in which the serious problems of medical etiquette are gravely discussed and judiciously decided. The editor of this ethical section has recently discussed the question of whether charges should be made for attendance upon the wives of medical men. The question is answered in the negative, and now the query is raised, should charges be made for attendance upon the husbands of medical women.

A Railway Surgeon in Trouble.—The path of the Western railway surgeon is not always strewn with roses. Dr. R. V. Smith, of Cleveland, O., was recently sued for $25,000 for an alleged malpractice. The plaintiff was a man who was injured while working for one of the Western railroads, of which Dr. Smith was the surgeon. The company is said to have settled with the patient for a certain sum of money, but, despite this, the plaintiff claims damages for maltreatment, and we presume that the company will promptly deny its responsibility, and shift it on to their poor servant, the railway surgeon. At any rate, it is stated that railway surgeons, who work under contract, are not thereby necessarily protected from malpractice suits. The companies, to be sure, generally protect the surgeons, but they are not obliged to do so.

Antirabic Sero-Therapy.—*The Lancet* publishes a series of articles by Drs. Tizzoni and Centanni on the subject of the use of the serum of animals protected against rabies. Their investigations extended over a long period, and the conclusions they have reached seem the result of a very careful work. They assert that by taking the serum of animals that have been protected against rabies, and preparing this for digestion by means of pepsin, they have secured an antirabic serum which protects animals better than is done by the original Pasteur method. The value of this preparation has so far been only tested upon animals, but if it should prove to be what its originators claim, it will do away with the expense of Pasteur institutes, for the serum can be dried or made antiseptic, and kept so that anyone can use it. It is to be hoped, therefore, that the new antirabic serum will really prove to be of value.

Artificial Human Milk.—A Berlin physician has devised what seems to be a rather novel method of imitating the modern milk. Cow's milk is fermented by means of rennet, and the whey thus obtained is carefully sterilized, and then enriched, as required by different individuals, by the addition of cream.

The Medical and Surgical Reporter has moved back its publishing office to Philadelphia.

Obituary.

FREDERIC M. WARNER, M.D.,

NEW YORK.

Dr. Frederic M. Warner died at his residence in this city on October 9th, at the age of thirty-eight. A man of bright attainments, of sterling professional zeal, of brilliant future promise—his death is not alone a loss to the medical fraternity, but also to the community.

Dr. Warner was born in Jersey City, July 14, 1857. He was educated at Lehigh University, and was graduated at the College of Physicians and Surgeons, New York.

After a protracted sojourn in Europe, he began the practice of medicine in this city in 1881, and at the time of his death he had acquired a large general practice, and for a man of his years no inconsiderable consulting work. His special leaning was toward internal medicine in particular diseases of the heart and lungs. In these affections he was a most astute diagnostician, and he possessed the rare faculty of being able to impart his knowledge to others in terse, descriptive terms, which marked him as a brilliant, clinical teacher. His solicitude for the patients under his charge at the City and the French Hospitals will long be remembered by his colleagues. His unique devotion to his patients, whether pauper or rich, irrespective of personal comfort or health, profoundly impressed those who had the privilege of knowing him well. He was just beginning to publish in the medical press the results of his observations in hospital and in private practice, and he was of material assistance to Dr. J. Lewis Smith, in the preparation of the last edition of "Diseases of Children." From the inception of the enterprise he had contributed to the "Annual of the Medical Sciences" (Sajous).

At the time of his death, Dr. Warner was a member of the Committee on Library of the Academy of Medicine, and of the Committee on Ethics of the County Medical Society. He was visiting physician to the City Hospital, and special consultant for heart and lungs at the French Hospital.

Reserved in manner, upright in action, steadfast in purpose, those who were admitted to his friendship could not help but love as well as admire him. Although young, he has left an impress suggestive of a most brilliant future.

Dr. Warner was married to a daughter of Dr. J. Lewis Smith. The widow and two children survive him.

Reviews and Notices.

Atlas of the Diseases of the Skin. By H. Radcliffe Crocker, M.D., F.R.C.P. Physician to the Department for Diseases of the Skin, University College Hospital; formerly physician to the East London Hospital for Children, etc. Edinburgh and London: Young J. Pentland. New York: Macmillan & Co.

Fasciculus Eleven of this series of plates has now been published. The illustrations comprise: Lichen Planus Acutus; Lymphangiectodes; Papilloma, with Xeroderma Pygmentosum, Milium, Acne Vulgaris, and Tinea Circinata.

The first represents, in a striking manner, acute lichen planus of the trunk; the arms being free. The second plate has four figures showing groups of lesions of different appearance upon the trunk, neck, and inner surface of the lip. The picture of xeroderma resembles closely the other cases which have become familiar, but shows, in addition to the characteristic lesions, a large papilloma occupying the region of the ear. The next plate illustrates, very well, milium in an infant, showing in a second figure lesions upon the hand, and in another, grouped lesions about the eyelids in an adult. Fig. 4 is a group of milium following pemphigus; and Fig. 5, grouped comedones of childhood.

Two large figures are devoted to acne; one beautifully showing acneiform folliculitis of the buttocks, the other being of a rather aggravated type of acne vulgaris of the back. The last plate has four figures, the largest being of a map-like ringworm involving the trunk and arms of a child; the other showing different varieties of lesion upon the nape of the neck, the arm, and buttock. In the latter the circular patch has not cleared in the centre, and the whole area is filled with minute papules more or less covered with fine scales. The general high character of the work, to which we have already referred, is being maintained both in text and illustration.

Practical Dietetics, with Special Reference to Diet in Disease. By W. Gilman Thompson, M.D., Professor of Materia Medica, Therapeutics, and Clinical Medicine in the University of the City of New York; Visiting Physician to the Presbyterian and Bellevue Hospitals. New York: D. Appleton & Co. 1895.

Dr. Thompson has rendered good service in preparing this volume on dietetics, for the subject is one upon which comparatively little has been written, and concerning which, it is safe to say, even less is known by the ordinary physician. Yet no one will dispute that the regulation of the diet in many diseases is at least as important as the administration of drugs.

The first chapters are devoted to a description of the various foods, their mode of preparation, and their value in nutrition. Following these is a chapter upon digestion and the special conditions which affect it favorably or injuriously. Then the author takes up the subject of diet in disease, devoting to this the second half of the work. After treating upon the diseases caused by improper food, by over-eating, or under-eating, the subject of feeding the sick is taken up, and treated in general very satisfactorily. The concluding pages of the book contain a chapter on army rations, hospital dietaries, milk, grape, and other "cures," athletic training, the relation of diet to occupation, etc.

The work will be found a useful supplement to the accepted treatises in therapeutics.

Medical and Surgical Reports of the Boston City Hospital. Sixth Series. Edited by George B. Shattuck, M.D., W. T. Councilman, M.D., H. L. Burrell, M.D. Boston: Published by the Trustees. 1895.

This excellent publication, which the editors announce will probably be henceforth an annual, contains twenty-five papers and reports upon the cases treated in the Boston City Hospital during the past year, embracing a great variety of subjects.

Index Catalogue of the Library of the Surgeon-General's Office, United States Army. Vol. XVI., W–Zythus. Washington: Government Printing Office. 1895.

This volume, which is probably the last to be issued under the personal supervision of Dr. Billings, completes the alphabet and is therefore the final volume of the first series. The second series, including the titles of books and articles received too late for insertion in the first series, of which the manuscript is already prepared, will comprise five volumes of the same size as those of the first series. An appropriation for the printing of this first volume has been made by Congress, and we are therefore assured that there will be no delay in its publication or in that of those that are to follow.

Transactions of the Medical Society of the State of Pennsylvania, at its Forty-fifth Annual Session, held at Chambersburg, 1895. Vol. XXVI. Philadelphia: The Edwards & Docker Co. 1895.

Transactions of the Medical Society of the State of California, Session of 1895. San Francisco: W. A. Woodward & Co. 1895.

These reports of the meetings of two of the most important State societies contain a number of valuable and interesting papers. It is to be regretted, however, that they should be practically buried in this way, instead of being given to the world through the columns of some live journal.

Text-book of Practical Therapeutics. By Hobart Amory Hare, M.D., B.Sc.; Professor of Therapeutics and Materia Medica, Jefferson Medical College, etc. Fifth Edition. Enlarged and thoroughly Revised. 8vo, pp. 740. Philadelphia: Lea Brothers & Co. 1895.

The fifth edition of this admirable work has been somewhat enlarged and thoroughly revised. A distinguishing feature of the work is a discussion of the antitoxin treatment of diphtheria. The author is a believer in this new method, and gives a very lucid description of its rationale, embodying the advanced views on the subject. As we have remarked concerning previous editions, the work is of exceptional value to the general practitioner who is ambitious of obtaining the most recent and advanced views of leading therapeutists, as well as the opinion of an acknowledged authority.

The Science and Art of Obstetrics. By Theophilus Parvin, A.M., M.D., LL.D.; Professor of Obstetrics and Diseases of Women and Children, Jefferson Medical College, Philadelphia, etc. 8vo, pp. 685. Philadelphia: Lea Brothers & Co. 1895.

The general plan of this classical work remains substantially unchanged in its third edition, although some of the subjects have a different order. Additions of great practical value have been made, and nearly one-third of the work has been rewritten. As a whole it is destined to maintain its hold in obstetric literature as one of the leading works of its kind. The experience of the author as a veteran teacher gives him great advantages in the practical treatment of his subjects, which, added to a perspicuous and graceful style, leave nothing to be desired in the full appreciation of a model of its kind.

A System of Surgery. Edited by Frederick Treves, F.R.C.S. Surgeon to and Lecturer on Surgery, London Hospital, etc. Vol. I., pp. 1152. Philadelphia: Lea Brothers & Co. 1895.

The progress which surgery has made during the past few years has made its impress upon the literature of its art and practice. The richness and extent of contributions in that line are manifest by the number of excellent treatises that are constantly making their appearance, giving the experience of the leading teachers. Mr. Treves's work is one of these, which is destined, as far as can be judged by the showing in the first volume now before us, to take a leading place. Following what appears to be the better accepted plan of special contributors to different departments, he has secured as his collaborators many of the leading surgeons of Great Britain. Each writer has striven, from a concise and practical standpoint, to exhaust his subject within the space allotted, and to carry out the spirit of the treatise by "presenting concisely and with authority an account of the science of surgery as it exists at the present day." The illustrations are numerous, well placed, and are mostly original in character. Two plates are introduced showing the bacteriological character of infectious discharges, but are hardly up in point of detail execution to the other illustrations so plentifully and judiciously sprinkled throughout the text. The number and variety of subjects treated in the present volume can be duly estimated by the following list: Surgical Bacteriology, by German Sims Woodward, M.D.; Inflammation, Suppuration, Ulceration, Gangrene, Syncope, Shock, and Wounds and Contusions, by W. Watson Cheyne, F.R.S., F.R.C.S.; Erysipelas, Pyæmia,

Tetanus, Tetany, Burns, and Scalds, by C. B. Lockwood, F.R.C.S.; Military Surgery, by Surgeon-Major Andrew Duncan, I.M.S., etc.; Anæsthetics, by Frederick W. Hewitt, M.D.; Infectious Surgical Diseases and Rickets, by George Henry Makins, F.R.C.S.; Tuberculosis, Rickets, Hæmophilia, and Surgical Hysteria, by the Editor, Frederick Treves, F.R.C.S.; Syphilis and Gonorrhœa, by Jonathan Hutchinson, Jr., F.R.C.S.; Injuries and Diseases of Blood-vessels, and Aneurism, by A. Pearce Gould, M.S., Lond.; Injuries and Diseases of the Lymphatics, by John H. Morgan, F.R.C.S.; and lastly, Injuries and Diseases of the Nerves, by Anthony Bowlby, F.R.C.S.

To such as are acquainted with Mr. Treves's Operative Surgery, no prediction will be necessary for the success of the present work.

Progress of Medical Science.

The Paralysis of Infancy.—The following convenient classification of these paralyses is given by the Madrid correspondent of the *Medical Press:*

Painful Paralysis of Children.—Was described by Chassaignac in 1855, and by Brunon in 1893. It is a temporary functional paralysis, of which the pain is an essential symptom. Prognosis is favorable. Diagnosis is made by the evanescent character of the affection, and the pain accompanying it, though there is no lesion of the articulations or bones.

Syphilitic Pseudo-Paralysis of Parrot.—Occurs only in infancy. The epiphyses are attacked, and crackling can be got between the epiphysis and the diaphysis as if they were separated. The affected limb appears totally paralysed. The muscles of the face, neck, and of respiration are never affected. No sensory troubles, except pain on movement. The sphincters are not affected. Electrical examination gives negative results.

Cerebro-spinal Syphilis.—The paralysis involves also the face; the epiphyses are not affected.

Syphilitic Paralysis of Peripheral Origin.—Diagnosis is based on the fact of the integrity of the bones, and on the modification of the electric reaction. When the syphilitic origin of the paralysis is not clear, diagnosis from infantile paralysis is made by considering the rapidity and fever with which this latter presents itself, the generalness of the paralytic phenomena, and the absence of pain.

Little's Malady.—Is a congenital spasmodic paraplegia of the four extremities, more marked in the lower, and occurring in children born prematurely. It is not accompanied by convulsions or psychical phenomena. It cannot be confounded with spasmodic tabes, for this belongs to adolescence and tends to grow worse.

Spasmodic Infantile Hemiplegia.—Is congenital, or manifests itself soon after birth; begins with convulsions. There are athetetic movements with convulsive crises, which, when they are bilateral, may be confounded with epilepsy. There is loss of intelligence, if not idiocy. The growth of the bones is hindered. As etiological factors, cysts, areas of cerebral softening, meningeal hemorrhage, meningo-encephalitis, and sclerosis have been found.

Friedreich's Disease (Hereditary Ataxy).—Does not present phenomena of motor inco-ordination. Is not congenital. Nystagmus and defective speech are present. The lightning pains, anæsthesia, and trophic changes of locomotor ataxy are wanting.

Primary Myopatias.—Pseudo-hypertrophic paralysis and atrophic myopatia are forms which present themselves in childhood. Thomsen's malady is a congenital form characterized by spasmodic rigidity of the voluntary muscles, which shows itself on beginning to make a movement.

Infantile Paralysis.—There is initial fever. The paralysis affects many muscles at first, and then becomes restricted to groups of muscles, or individual muscles. No sensory disturbances, and the intelligence remains normal.

Pott's Paralysis.—Frequent in infancy and youth. Follows disease of the dorso-lumbar vertebræ.

Diphtheritic Paralysis.—There is the history. An important symptom is the dysphagia and regurgitation of food by the nose.

Post-Morbillic Paralysis.—This occurs during convalescence; of paraplegic type; and after some six weeks ends in recovery.

Obstetric Paralysis.—Caused by traumatism inflicted at birth; the muscles usually affected are those supplied by the brachial plexus or facial nerve.

Hysterical Paralysis.—In these the reflexes are not abolished. Diagnosis by exclusion.

Choreic Paralysis.—Affects the monoplegic or hemiplegic form. Sometimes the paralysis precedes the chorea. Ordinarily it is post-choreic, or during the evolution of the neurosis.
